In this study we found significant elevations in the right and left ventricular output indexes and the combined ventricular output index of anemic fetuses compared with a control group. These differences could not be explained on the basis of greater heart rates, larger valve diameters, or smaller fetuses in the anemic group.

The fetal hematocrit level was not significantly correlated with cardiac output indexes of either ventricle or the combined ventricular index. The absence of such a finding might be postulated to relate to different stages of disease. Earlier stages might elevate output, with a depression in output at a later stage. This speculation is supported by the depressed output seen in the most severely ill fetus as previously mentioned.

The relationship between fetal anemia and increased cardiac output is uncertain in origin. Fumia et al.[14] found no change in combined ventricular output in sheep fetuses made acutely anemic by exchange transfusion. The mechanism for our findings is unlikely to be hypoxia. Although an increase in lactate concentrations have been reported in anemic fetuses,[15] this was most remarkable in the umbilical artery when the hemoglobin level was <4 gm/dl (hematocrit, 12%). Only three of 11 fetuses in the present study had hematocrit values below 12%. Tachycardia might have been anticipated in the presence of significant tissue hypoxia, but no relationship with fetal hematocrit was found ($r = 0.12$, $p = 0.69$ for right heart rate; $r = 0.43$, $p = 0.14$ for left heart rate [different heart rates result from beat-to-beat measurement of Doppler cycles]).

The performance of Doppler-based estimations of absolute flow is potentially influenced by a number of sources of error. In the present study these include angle estimation, waveform digitization, atrioventricular valve measurement, and estimation of fetal weight. The incident angles were minimized for all fetuses scanned and were similar in the anemic and control groups. Small errors would have been unlikely to systematically elevate the measurements in the anemic group only. Similar considerations apply to the digitization and valve measurement components of the cardiac output calculation.

A remaining concern is the effect of including hydropic fetuses. Because standard formulas for the estimation of fetal weight are based on biparietal diameter and abdominal circumference,[6] ascites would exaggerate fetal weight. We chose to use a mean for gestational age, as determined by menstrual history and sonography, in such situations. To compare the anemic and control groups independent of estimated fetal weight, formulas expressing stroke volumes and ventricular outputs as a function of gestational age were derived for the control group. The anemic fetuses retained their significant differences from the control fetuses. Because these two measurements were calculated independent of estimated fetal weight, inaccuracies in estimated fetal weight from inclusion of hydropic fetuses seem not to be the sole explanation for the differences found between the two groups. All the estimated fetal weights of the control group fell within 2 SD of the mean for gestational age, averaging 0.5 SD below the mean, thereby making elevated weight estimates and consequently lower cardiac indexes in control subjects unlikely to be the explanation for the differences seen.

We conclude that severely isoimmunized, anemic fetuses tend to have higher cardiac output than do control fetuses whether expressed as a function of estimated fetal weight or gestational age. The increase is shared proportionately by both ventricles. Some affected fetuses will have values in the normal range. Although the relationships described are significant, wide variations exist, making predictions of severity of the disease in the nonhydropic fetus unlikely to be accurate. Although there is no significant relationship between hematocrit values and cardiac output, extremely compromised fetuses may demonstrate diminished cardiac function as a terminal finding.

Further areas for investigation will include diastolic function of the ventricle, ventricular contraction characteristics, and longitudinal evaluation of the fetus over a course of intrauterine therapy. Finally, the basic cause of hydrops remains subject to speculation. Cardiac function must still be included as a potential part of

the explanation for why hydrops develops in the severely anemic fetus.

We gratefully acknowledge the patient care provided by the Yale Obstetrics and Gynecology housestaff and the nursing care provided by Mitzi Barger, RN, and Nancy Nickless, RN.

Twin-to-twin transfusion syndrome: What are appropriate diagnostic criteria?

Fiona H. Danskin, MB, ChB,* and James P. Neilson, MD
Glasgow, Scotland

One hundred seventy-eight consecutive twin pregnancies were studied to reevaluate the standard diagnostic criteria for chronic twin-to-twin transfusion syndrome of an intertwin hemoglobin difference >5 gm/dl and a birth weight difference >20%. Hemoglobin differences > 5 gm/dl were found in six pregnancies with monochorionic placentas but also in seven with dichorionic placentas. Birth weight differences >20% occurred no more commonly in monochorionic than in dichorionic pregnancies. Of the four pregnancies with a coexisting hemoglobin difference >5 gm/dl and birth weight difference >20%, only one had a monochorionic placenta and therefore likelihood of vascular anastomoses. Diagnosis of twin-to-twin transfusion syndrome cannot be definitively established by current standard diagnostic criteria. (AM J OBSTET GYNECOL 1989;161:365-9.)

Key words: Twin pregnancy, twin-to-twin transfusion syndrome, diagnosis

Twin-to-twin transfusion syndrome is an important complication of twin pregnancy,[1, 2] resulting from shunting of blood from one twin to the other through placental vascular anastomoses. Injection studies of twin placentas have shown that such anastomoses are almost universally present in monochorionic placentas

but so extremely rare in dichorionic placentas[1, 3] that the possibility of the syndrome occurring with this type of placenta can be disregarded. Both acute and chronic forms of the twin-to-twin transfusion syndrome have been described.[4, 5] The acute form has been attributed to rapid transfer of blood through superficial artery-to-artery or vein-to-vein anastomoses during labor and delivery, resulting in a hypovolemic, anemic donor twin and a hypervolemic, plethoric recipient twin of similar birth weight.[4, 5] The chronic syndrome results from gradual antepartum transfusion through deep artery-to-vein anastomoses, rendering the donor twin not only hypovolemic and anemic but also growth retarded, whereas the hypervolemic, plethoric recipient is usually larger.[6-8] These features may be accompanied by oligohydramnios in the sac of the donor and polyhydramnios in that of the recipient and may be identifiable before birth by ultrasonography.[9, 10]

Twin-to-twin transfusion syndrome is usually diagnosed or confirmed after birth by the discovery of a hemoglobin difference >5 gm/dl between twins[2] and a birth weight difference >20%, providing evidence of the chronic form of the syndrome.[4] We have reevaluated these standard and widely accepted diagnostic criteria as part of an ongoing intensive study of twin pregnancy. Despite an exhaustive MEDLINE literature search, we have not been able to identify any other such reevaluation.

Material and methods

One hundred seventy-eight consecutive twin pregnancies delivering in The Queen Mother's Hospital, Glasgow, (a tertiary referral center) between August 1984 and February 1988 were studied. Of the mothers, 160 had attended the hospital for antenatal care, mostly at a special twin pregnancy antenatal clinic, and the other 18 were transferred from other hospitals, usually in established or incipient preterm labor. Venous blood samples were usually obtained from neonates by pediatricians on the first day of life for hematologic indexes, including hemoglobin concentration. In some cases in which both babies were well, at term, and appropriate for gestational age, the pediatric staff considered venesection unnecessary on clinical grounds. All birth weights were recorded, and the intertwin birth weight difference was calculated as a percentage of the weight of the larger twin.

Zygosity was determined in 88% of pregnancies (Table I) by inspection of the placentas (a monochorionic placenta indicating a monozygotic pregnancy), sex discordance (indicating a dizygotic pregnancy), or when necessary by comparing red blood cell antigens of the ABO, rhesus, MNS, Kell, Duffy, Kidd, Lutheran, and Wright systems.[11] In all 21 cases in which zygosity was not established, the placenta was dichorionic and the twins were of like sex; in four there had been intrauterine death of one twin, and in the remainder blood was not sent for grouping.

Total perinatally related wastage, an index that includes late abortions, stillbirths, early and late neonatal deaths, and perinatally related infant deaths,[12] is shown in Table II. In all three monochorionic monozygotic pregnancies in which one or both fetuses were stillborn, features were compatible with, although not diagnostic of, twin-to-twin transfusion syndrome. In one preterm labor occurred at 34 weeks, and the leading twin died of asphyxia after abdominal dystocia caused by ascites; the second twin weighed 530 gm less and had a hemoglobin value at birth of 11 gm/dl. In another pregnancy acute polyhydramnios occurred in the amniotic sac of the first twin, which resulted in abruptio placentae and intrauterine death. The second twin, who survived, was very pale at birth and weighed 27% less than the first. In a third pregnancy acute polyhydramnios developed at 32 weeks, which was more marked in the amniotic sac of the first twin. Labor supervened within 24 hours and stillborn female infants were born; the first twin weighed 1.71 kg and appeared very plethoric with congested organs at postmortem examination, and the second twin weighed only 1.46 kg and appeared very pale. Hemoglobin values were not obtained in the latter two pregnancies.

Results

The hemoglobin concentrations of venous blood samples withdrawn from both babies on the first day of life were obtained in 118 of the 178 pregnancies. Both hemoglobin values were known in 35 of the 51 monochorionic pregnancies, and in six there was an intertwin difference >5 gm/dl. However, there were two pregnancies in the monozygotic dichorionic group, one in the dizygotic group, and four in the zygosity unknown group, all of which had dichorionic placentas, in which hemoglobin differences >5 gm/dl were also found. Oligohydramnios occurred in the amniotic sac of one twin in only two of these 13 pregnancies, both

Table II. Outcome in 178 consecutive twin pregnancies

of which had dichorionic placentas. None of the twenty-six babies in this group required treatment for anemia or polycythemia in the neonatal period.

Birth weight differences, which were expressed as a percentage of the weight of the larger twin, were calculated for all pregnancies. Excluding those cases in which there was a fetal abnormality or a fetus papyraceus, a birth weight difference >20% was present in 17.4% of pregnancies. The distribution of these according to zygosity is shown in Table III. Oligohydramnios was again an infrequent occurrence in this group and was found in the sac of one twin in only four pregnancies. Three of these had a dichorionic placenta and one had a monochorionic placenta.

In only four pregnancies did a hemoglobin difference >5 gm/dl and a birth weight difference >20% coexist, and none of these four pregnancies showed evidence of oligohydramnios or polyhydramnios in either amniotic sac. Only one of these pregnancies was associated with a monochorionic placenta, and in it alone did the heavier twin have the higher hemoglobin value (Table IV).

Comment

Since the recognition of the twin-to-twin transfusion syndrome by Herlitz[13] in 1941, much interest has been focused on this rare complication of twin pregnancy. Initial publications were single case reports of the syndrome, whereas larger studies later attempted to define the incidence, pathogenesis, and associated morbidity and mortality.[2, 4] It was suggested that when a large volume of blood is transferred antepartum, one or both twins may die in utero.[2] Since many early studies only considered those pregnancies resulting in the live birth of both babies, they probably underestimated the true incidence of the syndrome. In our study all three monochorionic pregnancies resulting in the stillbirth of one or both babies demonstrated features compatible with the twin-to-twin transfusion syndrome.

However, the purpose of our study was neither to determine the significance of the twin-to-twin transfusion syndrome in contributing to perinatal mortality and morbidity nor to define its incidence (we did not have hemoglobin values from all sets of twins). Rather, we aimed to reevaluate the standard diagnostic criteria for the twin-to-twin transfusion syndrome—a matter not only of clinical importance but also vital for further perinatal research.

Indeed, our study was generated by conflicting reports of fetal velocity waveforms of the umbilical artery as assessed by the new technology of Doppler ultrasonography on twin pregnancies believed complicated by the twin-to-twin transfusion syndrome. Concordant,[14] discordant,[15] and variable[16] patterns have been described, and these discrepancies may have stemmed from diagnostic confusion.

Twin-to-twin transfusion syndrome has traditionally been diagnosed after birth by finding a hemoglobin difference >5 gm/dl—a criterion introduced by Rausen et al.[2] in 1965. They had found such a hemoglobin difference in 19 of 130 monochorionic pregnancies, whereas in 43 dizygotic pregnancies no difference >3.3

Table IV. Birth weight difference >20% and hemoglobin difference >5 gm/dl

Zygosity/placentation	Birth weight			Hemoglobin		
	Twin 1 (kg)	Twin 2 (kg)	Difference (%)	Twin 1 (gm/dl)	Twin 2 (gm/dl)	Difference (gm/dl)
Monozygotic monochorionic	2.85	2.18	23.51	24.0	16.0	8.0
Monozygotic dichorionic	2.39	1.49	37.66	14.9	27.4	12.5
Dizygotic dichorionic	1.47	2.41	39.00	22.9	17.0	5.9
Dizygotic dichorionic	3.16	2.25	28.80	13.7	25.0	11.3

gm/dl was found. Therefore they selected a hemoglobin difference > 5 gm/dl as a suitable cutoff value, and this has been accepted by authors of subsequent publications as definitive evidence of the twin-to-twin transfusion syndrome. However, our study showed that although a hemoglobin difference > 5 gm/dl existed in six monochorionic pregnancies, it also occurred in seven dichorionic pregnancies; in fact the largest hemoglobin differences (12.5 and 11.3 gm/dl) occurred in the latter group. Because placental anastomoses are extremely rare in fused dichorionic placentas,[3] it is unlikely that the twin-to-twin transfusion syndrome occurred in these seven cases. Thus a difference in hemoglobin concentration is not in itself sufficient to establish a diagnosis of twin-to-twin transfusion syndrome.

Tan et al.[4] studied 482 twin pairs in an attempt to differentiate the acute and chronic forms of the syndrome. They diagnosed the syndrome in 35 sets of twins on finding obvious plethora in one twin and pallor in the other, along with a hemoglobin difference >5 gm/dl. They divided the twins into two groups according to whether the birth weight difference between each pair was greater or less than 20% of the weight of the heavier twin. They found that in those twins who had a large weight difference, the twin with the lower hemoglobin was invariably lighter, whereas in those twins with a small weight difference, the twin with the lower hemoglobin value was heavier. They concluded that birth weight difference provides a simple yet reliable yardstick for differentiation of twin pregnancies with hemoglobin differences into acute and chronic forms. This additional criterion of birth weight difference >20% has been widely adopted.

However, our study showed that a birth weight difference >20% occurred no more commonly in monochorionic pregnancies than in dichorionic pregnancies. In addition, of the four pregnancies in which a hemoglobin difference >5 gm/dl and a birth weight difference >20% coexisted, only one had a monochorionic placenta. In this pregnancy the heavier twin had the higher hemoglobin value, whereas in the three dichorionic pregnancies the lighter twin had the higher hemoglobin value. These presumably represent growth retardation in association with polycythemia, a well-recognized combination. Because Tan et al. used a hemoglobin difference >5 gm/dl as the sole diagnostic criterion for the twin-to-twin transfusion syndrome and did not take into account chorionicity of the placenta, it is likely that their subgroup included a similar proportion of polycythemic growth retarded babies from dichorionic pregnancies.

In summary, the standard diagnostic criteria used in clinical obstetrics and perinatal research do not permit a definitive diagnosis of the twin-to-twin transfusion syndrome. Differences in hemoglobin and birth weight must be interpreted in the light of knowledge of placental morphology and whether the heavier or lighter twin had the higher hemoglobin value. Further studies are still required to elucidate this enigmatic condition.

We gratefully acknowledge the contributions of Dr. A. A. M. Gibson, consultant pathologist, and the Regional Blood Transfusion Service, Law Hospital, in establishing zygosity, and the helpful criticisms of this manuscript by Professor C. R. Whitfield and Dr. B. Holland.

The prevalence and biologic significance of lupus anticoagulant and anticardiolipin antibodies in a general obstetric population

C. J. Lockwood, MD, R. Romero, MD, R. F. Feinberg, MD, PhD, L. P. Clyne, FIMLS, MS, B. Coster, BS, and J. C. Hobbins, MD

New Haven, Connecticut

Circulating antibodies to negatively-charged phospholipids have been implicated in the genesis of adverse pregnancy outcomes. However, it has yet to be established that these antibodies are causative or that they are invariably associated with untoward perinatal outcomes. To address this issue, the prevalence of lupus anticoagulant and anticardiolipin antibodies was recorded in a low-risk obstetric population, and the outcomes of untreated pregnancies were evaluated. Two of 737 patients (0.27%) had lupus anticoagulant documented by a prolonged activated partial thromboplastin time that did not correct with mixing studies. In comparison, greatly elevated concentrations of immunoglobulin M–anticardiolipin antibodies or immunoglobulin G–anticardiolipin antibodies were identified in 16/737 (2.2%) patients by means of an enzyme-linked immunosorbent assay. Spontaneous abortions occurred in both lupus anticoagulant–positive patients, suggesting that the activated partial thromboplastin time used was a relatively insensitive but specific marker for antiphospholipid antibody–associated adverse pregnancy outcomes. In contrast, although 12 of 16 anticardiolipin antibodies–positive pregnancies were complicated by perinatal loss, preterm delivery, or fetal growth retardation, four patients had uncomplicated pregnancies. Moreover, the distribution of anticardiolipin antibodies concentrations in these four patients was not clustered among the lowest anticardiolipin antibodies values, and anticardiolipin antibodies concentrations correlated weakly with adverse outcomes. These findings suggest that antiphospholipid antibodies are related to adverse pregnancy outcomes in a complex fashion and that therapy is not always required for acceptable outcomes in patients without other risk factors. (Am J Obstet Gynecol 1989;161:369-73.)

Key words: Lupus anticoagulant, anticardiolipin antibodies, activated partial thromboplastin time

Circulating lupus anticoagulants are either identical to or closely associated with immunoglobulin M (IgM) and immunoglobulin G (IgG) antibodies to negatively-charged phospholipids.[1] A laboratory characteristic of lupus anticoagulant is the inhibition of the activated partial thromboplastin time and its derivative assays.[1] This in vitro laboratory phenomenom is a consequence of antibody binding to negatively-charged phospholipid surfaces on which factors Xa and Va convert prothrombin to thrombin.[1] Paradoxically, in vivo lupus anticoagulant and related antiphospholipid antibodies promote thrombosis[1] via a myriad of potential prothrombotic mechanisms.[2-6]

Reportedly 94% of pregnancies occurring in patients with lupus anticoagulant who do not receive appropriate treatment result in spontaneous abortion or stillbirth.[7] A 13% to 40% prevalence of antibodies to the divalent phospholipid, cardiolipin, has been noted in patients evaluated for a history of "idiopathic" recur-

* Lupus anticoagulant–positive.

rent abortion.[8, 9] These observations lend credence to the hypothesis that antiphospholipid antibodies are directly responsible for the associated pregnancy wastage. Intervillous thrombosis,[7] spiral artery vasculopathy,[10] and immune-mediated trophoblast damage[11] are the postulated pathologic mechanisms. The presumed link between adverse pregnancy outcomes and antiphospholipid antibodies is so convincing that aggressive treatment has been advocated in "at risk" patients despite a lack of prospective, double-blind, placebo-controlled trials.[7]

This study was designed to establish the prevalence and biologic significance of lupus anticoagulant and antiphospholipid antibodies in a low-risk obstetric population. A prevalence of antiphospholipid antibodies in a low-risk obstetric population similar to that in populations with recurrent pregnancy wastage would be evidence against the pathogenicity of these antibodies. Normal outcomes in untreated, low-risk patients with the antibodies would also contradict a pathogenic role, as would a lack of correlation between antiphospholipid antibody concentration and adverse pregnancy outcomes.

Material and methods

Patient population. The study population was derived from the Yale–New Haven Hospital obstetric clinic. The investigation was approved by the Yale Human Investigation Committee and informed consent was obtained. Patients with a history of three consecutive spontaneous losses or stillbirths were excluded, and a total of 737 sequential eligible patients were enrolled during a 9-month study period. One additional citrated plasma and serum sample was obtained from each study patient undergoing phlebotomy during routine obstetric care. The samples were placed on ice, centrifuged at 5000 rpm for 10 minutes, and the supernatant frozen in multiple aliquots at −70° C for 4 to 8 months. Prior studies have demonstrated that lupus anticoagulant effect is preserved for prolonged periods after similar storage.[12]

Identification of lupus anticoagulant effect. The presence of lupus anticoagulant was assessed by activated partial thromboplastin time. The partial thromboplastin reagent consisted of cardiolipin- and phosphotidylserine-rich mixed-brain phospholipid. Colloidal silica was used as the activator, and an automated method was used (MLA-Electra 600, Medical Laboratory Automation, Inc., Mount Vernon, N.Y.). The activated partial thromboplastin time recorded was the average of duplicated determinations. Pooled plasma from nonpregnant patients was used with each run as a control. Mixing studies were performed on prolonged samples with the use of a separate aliquot of the patient's citrated plasma and an equal quantity of control plasma.

Detection of antiphospholipid antibodies: Anticardiolipin antibodies enzyme-linked immunosorbent assay. Anticardiolipin antibodies were isolated by means of an enzyme-linked immunoabsorbent assay that was developed by Cowchock et al.[8] Microtiter plates (Fisher Scientific Co., Springfield, N.J.) were coated with 1 μg of bovine cardiolipin in ethanol (Sigma Chemical, St. Louis, Mo.), air evaporated in a cold room overnight, and blocked with fetal calf serum. Uncoated plates were similarly blocked. The wells were then successively incubated with test or control serum, goat antihuman γ- or μ-chain IgG (Sigma), and alkaline phosphatase conjugated–rabbit antigoat γ-chain IgG (Sigma). The plates were washed with a Titertek Washer (Flow Laboratories, McLean, Va.) with phosphate-buffered saline solution between incubations. The substrate 4 *p*-nitrophenylphosphate was then added for 1 hour in a dark room, and the subsequent colorimetric reaction was read at 405 nm with Multiskan Plus microtiter plate reader (Flow Laboratories).

A standard linear curve was then generated on log-logistic paper of the Δ optical density 405 nm readings from serial dilutions of positive control serum containing known concentrations of IgM or IgG anticardiolipin antibodies. Dilutions of both control sera and antibody reagents were chosen to yield a maximal absorbance of 0.8 at 405 nm. Average IgM or IgG anti-

cardiolipin antibody units were assigned to each patient's duplicated sample by plotting against the standard curve. All elevated samples were repeated, and only those samples found elevated in two separate assays were considered significant.

Since polyclonal elevations of IgM and IgG may cause false-positive readings as a result of nonspecific binding, only specific binding to cardiolipin was considered diagnostic. This was calculated by subtracting the total IgM or IgG unit values obtained in the cardiolipin-coated plates from the nonspecific IgM or IgG unit values obtained in the uncoated plates.

Data collection and analysis. All assays were performed by one investigator (C. L.) before the review of patient records. Demographic and outcome variables were collected after delivery. Nine subjects were lost to follow-up, and 22 patients had therapeutic abortions. Final outcome data were available for the remaining 706 patients.

Statistical analysis of the data was done by means of the Student *t* test, Mann-Whitney test, χ^2, Fisher's exact test, Z test for proportions, and multiple logistic regression.

Results

Population demographics on enrollment. The median gestational age at sampling was 16 weeks. The mean maternal age was 22.7 years (95% confidence interval 22.3, 23.1). Median gravidity was three and median parity was one. The racial distribution was 63% black, 18.5% white, and 18.5% Hispanic.

Outcomes in patients with lupus anticoagulant. The mean activated partial thromboplastin time of the study patients was 30.6 seconds (95% confidence interval 30.3, 30.9) and was not different from the nonpregnant control value of 30.5 seconds (95% confidence interval 30.4, 30.6). The activated partial thromboplastin time displayed a slight inverse correlation with gestational age at sampling ($R = -0.24$; $p < 0.0001$).

An activated partial thromboplastin time >2.3 standard deviations above the total population mean was considered abnormal (equivalent to 1.3 multiples of the mean, or 40 seconds). This excluded 99% of the unaffected population. Two patients demonstrated an activated partial thromboplastin time >40 seconds, which did not correct on mixing studies, thus giving a lupus anticoagulant prevalence of 0.27%. Both of these patients had midsecond-trimester losses and false-positive syphilitic serologic studies (case 1 activated partial thromboplastin time = 45.0/30.2 seconds; case 2 activated partial thromboplastin time = 42.6/28.0 seconds). After correcting for gestational age at sampling, the activated partial thromboplastin time did not correlate with birth weight or gestational age at delivery.

Outcomes in patients with anticardiolipin antibodies. The distribution of IgM and IgG anticardiolipin antibody concentrations was evaluated in a population subset with normal outcomes (nongrowth retarded, term, live births). This distribution was positively skewed. However, the natural log transformation of the data was normally distributed. A concentration greater than 2.3 SD above the transformed mean was chosen as a cutoff value, since this excluded 99% of unaffected patients.

IgM and IgG anticardiolipin antibody concentrations did not correlate with the activated partial thromboplastin time or gestational age at sampling. There were significant differences between mean activated partial thromboplastin time in the anticardiolipin antibody–positive (33.0 seconds, 95% confidence interval 30.73, 35.29) versus the anticardiolipin antibody–negative (30.5 seconds, 95% confidence interval 30.26, 30.86) populations ($p < 0.015$). With a 2.3 SD cutoff value, seven patients had elevated concentrations of cardiolipin-specific IgM, and 12 patients had elevated concentrations of cardiolipin-specific IgG. The anticardiolipin antibody concentrations in SD above the mean and the pregnancy outcomes are presented in Table I.

A total of 16 patients had either IgM or IgG anticardiolipin antibodies, resulting in a 2.2% prevalence of anticardiolipin antibodies in this low-risk population. There were no differences in maternal age or parity between the affected and unaffected populations. However, patients with elevated anticardiolipin antibodies levels were more likely to have had a prior spontaneous abortion or preterm delivery ($p < 0.0001$). The anticardiolipin antibody–positive population had significantly different pregnancy outcomes compared with the unaffected population (Tables II and III). Patients with anticardiolipin antibodies were noted to deliver at earlier gestational ages and have lower mean

birth weights compared with the unaffected population. The anticardiolipin antibody–positive population had a fivefold relative risk of having a spontaneous abortion or low birth weight infant compared with the anticardiolipin antibody–negative population. Patients with anticardiolipin antibodies were more frequently Hispanic and smokers, although these differences did not attain statistical significance.

Ten patients in the study population had a false-positive rapid plasma reagin test; five were positive for anticardiolipin antibodies. Three of the five anticardiolipin antibody–negative patients with a false-positive rapid plasma reagin test had greatly elevated (>3 SD) nonspecific IgM binding, which suggested polyclonal IgM elevations. Two of these three patients were human immunodeficiency virus positive.

Multiple stepwise regression analysis demonstrated a weak inverse correlation between IgM anticardiolipin antibody concentrations and birth weight ($R = -0.26$, $R^2 = 0.07$, $p = 0.025$). No statistically significant correlations were demonstrated for IgG anticardiolipin antibody concentrations and birth weight or for IgM or IgG anticardiolipin antibody concentrations and gestational age at delivery.

Comment

The prevalence of lupus anticoagulant as ascertained by activated partial thromboplastin time was 0.27% in this low-risk obstetric population. The two affected pregnancies resulted in mid-gestational losses. However, the activated partial thromboplastin time was able to detect only two of 16 (12.5%) patients with antiphospholipid antibodies identified by an anticardiolipin antibodies enzyme-linked immunosorbent assay. We conclude that the particular activated partial thromboplastin time used in this low-risk population has low sensitivity but high specificity for the prediction of adverse pregnancy outcomes in patients who also had antiphospholipid antibodies.

Prior studies have demonstrated that the activated partial thromboplastin time will identify 80% to 90% of patients harboring lupus anticoagulant detectable by more elaborate coagulation assays.[13] The relative insensitivity of the activated partial thromboplastin time used in this study is unlikely to have resulted from antibody absorption by platelet phospholipid, since centrifugation had rendered the samples platelet poor. The use of mixed-brain phospholipid as the partial thromboplastin may have reduced efficiency, since it has been shown to be less sensitive than synthetic preparations.[13] Alternatively, functional coagulation assays that detect the indirect effect of antiphospholipid antibodies on in vitro prothrombin complex formation may simply be less sensitive than direct assays for the presence of antiphospholipid antibodies. A number of investigators have noted this relative insensitivity.[8, 11, 14]

Both patients with lupus anticoagulant had either IgM or IgG anticardiolipin antibodies; however, concentrations of anticardiolipin antibodies did not correlate with activated partial thromboplastin time in the 16 patients with elevated concentrations of anticardiolipin antibodies or with concentrations in the general population. This is in contrast to other investigators who have demonstrated a significant correlation ($r = 0.702$) between the kaolin partial thromboplastin time and IgG anticardiolipin antibody activity.[15] The lack of correlation between anticardiolipin antibody concentration or immunoglobulin class and activated partial thromboplastin time prolongation suggests that the insensitivity of the coagulation assay is not simply a quantitative- or immunoglobulin class–dependent phenomenon.

The prevalence of elevated concentrations of cardiolipin-specific IgM or IgG was 2.2% in this low-risk obstetric population. This frequency is comparable with the 2.1% (2/94) prevalence of anticardiolipin antibodies found by Petri et al.[14] in a sample low-risk, pregnant population derived by use of a 97.5% confidence interval cutoff in a positively skewed distribution. The sensitivity of the anticardiolipin antibody enzyme-linked immunosorbent assay in identifying the presence of any antiphospholipid antibody production has been reported at >80%.[8] Nonetheless, the failure to evaluate other potential phospholipid epitopes may have resulted in a modest underestimation of the prev-

alence of antiphospholipid antibody–mediated pregnancy wastage in this study. Furthermore, the relatively late median date of sampling may have caused the exclusion of a number of patients with spontaneous abortions and therefore underestimated the prevalence of anticardiolipin antibodies.

Although 12 of 16 patients (75%) with anticardiolipin antibodies had adverse perinatal outcomes, including spontaneous abortions, stillbirths, preterm delivery, or growth retardation, these adverse outcomes were not invariable. Moreover, the concentration of the antibody was only weakly correlated with adverse outcomes. The distribution of anticardiolipin antibody concentrations in the four patients with normal pregnancy outcomes was not clustered among the lowest concentrations, suggesting that a higher cutoff value would not have eliminated these patients but would have lowered sensitivity for the prediction of adverse pregnancy outcomes. Furthermore, the cutoff value used in this study after log transformation of the data corresponded to 6 SD above the mean of the original nongaussian distribution. This is a far-higher cutoff value than has been used by a number of other investigators[8, 9, 11, 14] and is comparable with the optimal cutoff value suggested by Harris et al.[16] Thus adverse pregnancy outcomes do not appear to be an invariable consequence of antiphospholipid antibodies. This suggests that therapy is not always required to achieve normal outcomes.

The complex relationship between anticardiolipin antibodies and both adverse pregnancy outcomes and activated partial thromboplastin time inhibition demonstrated in this study may be a consequence of a number of biologic modifiers. Heterogeneity in antibody effect may result from individual variations in antibody affinity and avidity or from variations in the stimulus for anticardiolipin antibodies production (e.g., anticardiolipin antibodies produced in response to syphilis or viral infections are not associated with thrombosis). A second modifier of the biologic effect of antiphospholipid antibodies is host resistance. Patients with greater endothelial surface concentrations of antithrombin III, protein C and S, or prostacyclin synthetase may be less susceptible to the potential adverse consequences of antiphospholipid antibodies. Variation in membrane phospholipid content caused by dietary or genetic factors may also modify host resistance to antibody effect.

We acknowledge the assistance of Ms. Kathleen Costigan in the statistical analysis of the data and the advice and technical assistance of Dr. Susan Cowchock and Ms. Denise Ruch in establishing the anticardiolipin antibody enzyme-linked immunosorbent assay.

Fetal blood gas analysis from cordocentesis for abnormal fetal heart rate patterns

Dinesh M. Shah, MD, and Frank H. Boehm, MD
Nashville, Tennessee

We present three cases with abnormal fetal heart rate patterns and cordocentesis umbilical venous blood gas analyses. Conflicting heart rate patterns and cordocentesis and postnatal blood gas analyses prompt questions with regard to abnormal fetal heart rate pattern interpretation and suggest that cordocentesis blood gas analysis aids perinatal management only as a reflection of fetal status at sampling time. (AM J OBSTET GYNECOL 1989;161:374-6.)

Key words: Cordocentesis, fetal blood gas analysis, fetal heart rate patterns

Fetal blood sampling through ultrasonography-guided needle puncture of umbilical cord was suggested by Hobbins et al.[1] for prenatal assessment of fetal hypoxia. Nicolaides et al.[2] reported diagnosis of severe hypoxic acidosis by fetal blood sampling in a case of symmetrical intrauterine growth retardation.

We used fetal blood sampling and subsequent blood gas analysis for in utero assessment of fetal status in three cases, which provided interesting results used in clinical management. Dilemmas that arose from conflicting fetal heart rate tracings, cordocentesis-obtained umbilical venous blood gas analysis, and postnatal cord gas analysis are presented.

Case 1

B. H., a 31-year-old gravida 2, para 0-0-1-0 woman at 24 weeks' gestation, transferred to Vanderbilt University Medical Center because of polyhydramnios and uterine irritability and was placed on oral tocolysis. External fetal heart rate monitoring revealed a basal rate of 140 to 150 beats/min and a flat baseline with frequent deep variable decelerations. Ultrasonography revealed polyhydramnios and double bubble sign consistent with diagnosis of duodenal atresia. The patient underwent fetal blood sampling to rule out chromosomal abnormality.

She was delivered of an infant 5 days after cordocentesis as a result of active preterm labor. The neonate weighed 630 gm, had respiratory distress, required duodenostomy, and was discharged on day 116 after birth. A representative monitor tracing and all results are presented in Fig. 1.

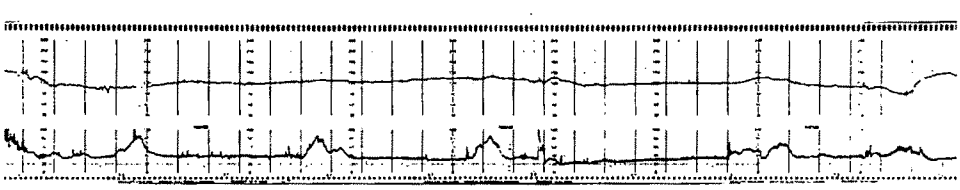
Case 2

J. B., an 18-year-old primigravid woman at 27 weeks' gestation, transferred to Vanderbilt University Medical Center because of preterm labor and was placed on intravenous and later oral tocolysis. Ultrasonography revealed biometry consistent with menstrual dates, a slightly increased amniotic fluid level. There were no notable anomalies. Biophysical profile revealed a score of 8 of 8. She had occasional spontaneous late decelerations, and persistence of variable decelerations was noted on day 5 with baseline rate in the 140s. Increased frequency of late decelerations with baseline rate in the 150s was noted on day 9. The patient was counseled and offered fetal blood sampling through cordocentesis. Fetal oxygenation and acid base status were within acceptable limits. While awaiting karyotype results, 24 hours after cordocentesis the patient had an acute drop in fetal heart rate to 60 beats/minuteand underwent emergency cesarean section. The newborn weighed 1120 gm with Apgar scores of 1 and 2 at 1 and 5 minutes, had respiratory distress, and was discharged to a level I center on day 39 of life. A representative monitor tracing and all results are presented in Fig. 2.

Case 3



T. A., a 22-year-old obese woman, was first seen at 29 weeks' gestation by ultrasonography with severe oligohydramnios detected 2 weeks before transfer. Vanderbilt University Medical Center ultrasonography revealed biometry consistent with 27 weeks' gestation, and there were no obvious anomalies. However, examination was limited as a result of the patient's obesity and oligohydramnios. Both kidneys and a small fluid-filled bladder were visualized. Fetal heart rate tracing revealed flat baseline with 145 beats/min and spontaneous frequent variable and late decelerations. Biophysical profile revealed a score of 0 of 8. The patient was counseled with regard to cordocentesis and the rationale for obtainment of fetal karyotype and blood gases.

PRENATAL ABG: pH 7.39, pCO_2 49 mmHg, pO_2 17 mmHg, base excess -5.8
POSTNATAL ABG: pH 7.39, pCO_2 44 mmHg, pO_2 16 mmHg, base excess -13.5

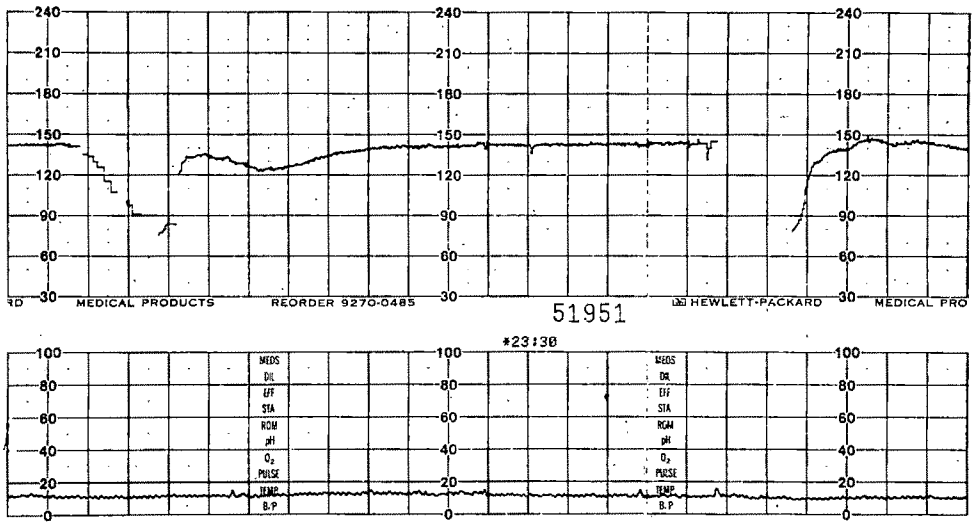


Fig. 1. Representative monitor tracing and fetal blood gas analysis results on fetus with duodenal atresia and normal male karyotype.

CASE 2

PRENATAL ABG: pH 7.25, pCO_2 48 mmHg, pO_2 29.9 mmHg, base excess -6.3
POSTNATAL ABG: pH 6.79, pCO_2 109 mmHg, pO_2 24 mmHg, base excess -19.6

Fig. 2. Representative monitor tracing and fetal blood gas analysis results on fetus with normal female karyotype that had bradycardia.

PRENATAL ABG: pH 7.11, pCO_2 73.6 mmHg, pO_2 8.5 mmHg, base excess -8.1
POSTNATAL ABG: pH 7.04, pCO_2 78 mmHg, pO_2 8 mmHg, base excess -9.4

Fig. 3. Representative monitor tracing and fetal blood gas analysis results on fetus with oligohydramnios and normal male karyotype.

She was delivered by immediate cesarean section of a 980 gm male with Apgar scores of 3 and 7 at 1 and 5 minutes, intrauterine growth retardation, and hyaline membrane disease. The infant was transferred to a level I center on day 57 after birth. A representative monitor tracing and all results are presented in Fig. 3.

Comment

Electronic fetal heart rate monitoring has been very useful in evaluation of fetal status. The clinical situations described herein characterize circumstances in which the obtainment of fetal blood gas information by cordocentesis may assist in management.

In Case 1, information with regard to normal fetal karyotype and blood gases through cordocentesis provided reassurance to the patient and assisted in expectant management. Abnormal postnatal gases in Case 2 are partially explained by the sustained fetal bradycardia that resulted in marked carbon dioxide retention. Differences between prenatal and postnatal gas analyses in Case 3 are easily explained because the prenatal sample was umbilical venous blood and the postnatal sample was umbilical arterial blood.

Our cases differ from previous reports in that gestational ages are significantly earlier and therefore the need for expectant management is even more critical if justified by blood gas information. In addition, each case had persistently abnormal fetal heart rate tracings that heightened the need for fetal blood gas information. Case 1 illustrates a dilemma in "accurate" interpretation of fetal heart tracing. Case 2 emphasizes that fetal blood gas analysis with cordocentesis sample reflects fetal status at sampling time only. In Case 3 blood gas results indicate fetal distress, which precipitates immediate cesarean section.

IN BRIEF:
TRIPHASIL®—6 brown tablets containing 0.050 mg levonorgestrel with 0.030 mg ethinyl estradiol; 5 white tablets containing 0.075 mg levonorgestrel with 0.040 mg ethinyl estradiol; 10 light-yellow tablets containing 0.125 mg levonorgestrel with 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day regimen)—Triphasic regimen.

Indications and Usage—TRIPHASIL® is indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OC's) as a method of contraception.

Contraindications—OC's should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5). 8. Benign or malignant liver tumor which developed during use of OC's or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems*—An increased risk of thromboembolic and thrombotic disease associated with use of OC's is well established. Three principal studies in Great Britain and 3 in the U.S. have demonstrated increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OC's are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS—In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION (MI)—An increased risk of MI associated with the use of OC's has been reported, confirming a previously suspected association. These studies, conducted in the UK, found, as expected, that the greater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of pre-eclamptic toxemia) the higher the risk of developing MI, regardless of whether the patient was an OC user or not. OC's, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to MI) are about twice as likely to have a fatal MI as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal MI compared to users who do not smoke, but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, amount of smoking is also an important factor. In determining importance of these relative risks, however, baseline rates for various age groups must be given serious consideration. Importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; quite likely the same synergistic action exists, but perhaps to a lesser extent.

RISK OF DOSE—In an analysis of data derived from several national adverse-reaction reporting systems, British investigators concluded that risk of thromboembolism, including coronary thrombosis, is directly related to dose of estrogen in OC's. Preparations containing 100 mcg or more of estrogen were associated with higher risk of thromboembolism than those containing 50-80 mcg. Their analysis did suggest, however, that quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the U.S.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES—A large prospective study carried out in the UK estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OC's according to age, smoking habits, and duration of use. Overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), risk being concentrated in older women, in those with long duration of use and in cigarette smokers. It was not possible, however, to examine interrelationships of age, smoking, and duration of use, nor to compare effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess magnitude of relative risk for this younger group. Available data from a variety of sources have been analyzed to estimate risk of death associated with various methods of contraception. Estimates of risk of death for each method include combined risk of contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OC's) plus risk attributable to pregnancy or abortion in event of method failure. This latter risk varies with effectiveness of method. The study concluded that mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OC's in women over 40 who smoke. Lowest mortality is associated with condom or diaphragm backed up by early abortion. Risk of thromboembolic and thrombotic disease associated with OC's increases with age after about 30 and, for MI, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of pre-eclamptic toxemia, and especially cigarette smoking. Physician and patient should be alert to earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A 4- to 6-fold increased risk of postsurgery thromboembolic complications has been reported in OC users. If feasible, OC's should be discontinued at least 4 weeks before surgery of a type associated with increased risk of thromboembolism or prolonged immobilization.

PERSISTENCE OF RISK OF VASCULAR DISORDERS—Findings from one study in Britain involving cerebrovascular disease and another in the U.S. concerning MI suggest an increased risk of these conditions in users of OC's persists after discontinuation of the OC's. In the British study, risk of cerebrovascular disease remained elevated in former OC users for at least 6 years after discontinuation. In the U.S. study, increased risk of MI persisted for at least 9 years in women 40 to 49 years old who had used OC's for 5 or more years. Findings in both studies require confirmation since they are inconsistent with other published information.

2. *Ocular Lesions*—There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with use of OC's. Discontinue OC's if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

3. *Carcinoma*—Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases frequency of carcinoma of the breast, cervix, vagina, and liver. Certain synthetic progestogens, none currently contained in OC's, have been noted to increase incidence of mammary nodules, benign and malignant, in dogs. In humans, 3 case-control studies have reported an increased risk of endometrial carcinoma associated with prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OC's. Of cases found in women without predisposing risk factors (e.g., irregular bleeding at the time OC's were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These are no longer marketed. No evidence has been reported suggesting increased risk of endometrial cancer in users of conventional combination or progestogen-only OC's. Several studies have found no increase in breast cancer in women taking OC's or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women on OC's, found an excess risk in subgroups of OC users with documented benign breast disease. Reduced occurrence of benign breast tumors in users of OC's has been well documented. In summary, there is at present no confirmed evidence from human studies of increased risk of cancer associated with OC's. Close clinical surveillance of all women on OC's is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or with breast nodules, fibrocystic disease, or abnormal mammograms should be monitored with particular care if they elect to use OC's.

4. *Hepatic Tumors*—Benign hepatic adenomas have been found to be associated with use of OC's. One study showed that OC's with high hormonal potency were associated with higher risk than lower potency OC's. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users. Two studies relate risk with duration of use of OC's, the risk being much greater after 4 or more years' use. While hepatic adenoma is rare, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women on OC's. Relationship of these drugs to this type of malignancy is not known.

5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring, and Malignancy in Female Offspring*—Use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have increased risk of developing in later life a form of vaginal or cervical cancer ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence now that OC's further enhance risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OC's. Furthermore, 30 to 90% of such exposed women have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with use of other estrogens, it cannot be presumed they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with use of sex hormones, including OC's, in pregnancy. One case-control study estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OC's, hormonal withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some exposures involved only a few days. Data suggest that risk of limb-reduction defects in exposed fetuses is somewhat less than 1 in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OC's. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OC's is unknown. It is recommended that, for any patient who has missed 2 consecutive periods, pregnancy should be ruled out before continuing OC's. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at time of first missed period, and further use of OC's should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and advisability of continuation of the pregnancy should be discussed. It is also recommended that women who discontinue OC's with intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this. The administration of progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease*—Studies report increased risk of surgically confirmed gallbladder disease in users of OC's and estrogens. In one study, increased risk appeared after 2 years' use and doubled after 4 or 5 years' use. In one of the other studies, increased risk was apparent between 6 and 12 months' use.

7. *Carbohydrate and Lipid Metabolic Effects*—Decrease in glucose tolerance has been observed in a significant percentage of patients on OC's. For this reason, prediabetic and diabetic patients should be carefully observed while on OC's. Increases in triglycerides and total phospholipids have been observed in patients on OC's. Three studies were performed with Triphasil and no significant alterations in lipid metabolism were noted except for a slight increase in triglyceride levels in 1 study. Clinical significance of these findings remains to be defined.

8. *Elevated Blood Pressure*—Increase in blood pressure has been reported in patients on OC's. In some women, hypertension may occur within a few months of beginning OC's. In the 1st year of use, prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. Prevalence in users increases, however, with longer exposure, and in the 5th year of use is 2½ to 3 times the reported prevalence in the 1st year. Age is also strongly correlated with development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure on OC's. Hypertension that develops as a result of taking OC's usually returns to normal after discontinuing the drug.

9. *Headache*—Onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of OC's and evaluation of the cause.

10. *Bleeding Irregularities*—Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing OC's. In breakthrough bleeding, as in all cases of irregular vaginal bleeding, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or change to another OC may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary, since this may increase risk of thromboembolic disease. Women with past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuing OC's. Women with these preexisting problems should be advised of this possibility and encouraged to use other methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy*—Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast-feeding*—OC's given in the postpartum period may interfere with lactation and decrease quantity and quality of breast milk. Furthermore, a small fraction of the hormones in OC's has been identified in the milk of mothers on OC's; effects, if any, on the breast-fed child have not been determined. If feasible, defer OC's until infant has been weaned.

Precautions—GENERAL—1. A complete medical and family history should be taken prior to initiation of OC's. Pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Pap smear and relevant laboratory tests. As a general rule OC's should not be prescribed for longer than 1 year without another physical examination and Pap smear.

2. Under influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size.

3. Patients with history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while on OC's should stop OC's and use an alternate method to try to determine whether the symptom is drug-related.

4. OC's may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency.

5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence while on OC's. If jaundice develops, OC's should be discontinued.

6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution.

7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. Clinical significance is undetermined.

8. Serum folate levels may be depressed by OC's. Since the pregnant woman is predisposed to development of folate deficiency and incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OC's, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency.

9. The pathologist should be advised of OC therapy when relevant specimens are submitted.

10. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containing OC's:

a. Increased sulfobromophthalein retention.

b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.

c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered.

d. Decreased pregnanediol excretion.

e. Reduced response to metyrapone test.

Information for the Patient—See Patient Package Labeling.

Drug Interactions—Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.

Carcinogenesis—See Warnings section for information on carcinogenesis.

Pregnancy—Category X. See Contraindications, Warnings.

Nursing Mothers—See Warnings.

Adverse Reactions—An increased risk of these serious adverse reactions has been associated with use of OC's (see Warnings): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, benign hepatomas, congenital anomalies. There is evidence of an association between the following conditions and use of OC's although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients on OC's and are believed to be drug-related. Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally. Gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea, amenorrhea during and after treatment, temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes; tenderness, enlargement, and secretion; change in weight (increase or decrease); change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening), intolerance to contact lenses. The following adverse reactions have been reported in users of OC's, and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, hemolytic uremic syndrome.

Acute Overdose—Serious ill effects have not been reported following acute ingestion of large doses of OC's by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Dosage and Administration—For maximum contraceptive effectiveness, Triphasil must be taken exactly as directed and at intervals not over 24 hours. (If Triphasil is first taken later than first day of first menstrual cycle of medication or postpartum, contraceptive reliance should not be placed on it until after the first 7 consecutive days of use. Possibility of ovulation and conception prior to initiation of medication should be considered.)

Any time patient misses 1 or 2 brown, white or light-yellow tablets, she should also use another contraceptive method until she has taken a tablet daily for 7 consecutive days.

For full details on dosage and administration see prescribing information in package insert.

KAISER PERMANENTE

OBSTETRICIAN-GYNECOLOGIST: BC/BE physician wanted full time or part time for satellite medical office practice in Gilroy, California, as part of The Permanente Medical Group, Inc., of San Jose, California. Excellent general Ob/Gyn outpatient skills required plus willingness to work with experienced Family Practice Physicians and Ob/Gyn nurse practitioners. Hospital call optional. Gilroy is located twenty minutes south of San Jose and shares excellent access to the Bay Area recreational activities. Salary is competitive and benefits include full coverage malpractice insurance.

Contact:
Jerome L. Nehemiah, M.D.
Chief
Department of OB/GYN
The Permanente Medical Group, Inc.
260 International Circle
San Jose, CA 95119

Or call: 408-972-6210 or 408-972-6113

MATERNAL-FETAL MEDICINE
(Board eligible or Certified)

600 Bed University-affilited Level III Hospital with 3,600 deliveries/year, 24-hour in-house Anesthesiology and Neonatology/large NICU, active maternal transfer service, perinatal outreach programs, and fully-approved OB/GYN residency program has immediate opening for a full-time position in Perinatology. Duties to include residency teaching, maternal transfer care, and private practice incentive. Competitive guaranteed salary plus incentive. Excellent public school system, housing, and Lake St. Clair in very close proximity.

CALL COLLECT: 313-343-3495
MINU KASHEF, M.D.
ST. JOHN HOSPITAL
DEPT. OB/GYN
DETROIT, MI 48236

PERINATOLOGIST
Denver, Colorado

Rose Medical Center, Denver, Colorado is seeking a second BE/BC perinatologist to work full-time in a 400-bed private community hospital adjacent to the University of Colorado Health Sciences Center. With 3,600 deliveries per year, and 27 University Residents rotating through the department annually, Rose is the major private teaching affiliate of the University.

Responsibilities include private consultation, physician, resident, and nursing education, clinical research, and a limited private practice in perinatology. This individual can expect frequent interaction with the Maternal/Fetal Medicine Division at the University of Colorado, and will be eligible for an appropriate clinical appointment at the University. All clinical responsibilities will be shared with the current full-time perinatologist at Rose.

A competitive salary guarantee is being offered, with excellent fringe benefits including malpractice insurance.

Qualified applicants, including individuals completing fellowship in June, 1989, should forward CV's to:

Robert E. Wall, M.D., Chairman
Department of Obstetrics & Gynecology
Rose Medical Center
4567 East Ninth Avenue
Denver, Colorado 80220
Telephone: (303) 320-2077

FELLOWSHIP
MATERNAL-FETAL MEDICINE
JULY, 1990

The Division of Maternal-Fetal Medicine, Department of Obstetrics and Gynecology, MacDonald Hospital for Women, University Hospitals of Cleveland, and Case Western Reserve University, has an opening at the instructor level beginning July 1, 1990. Applicants should desire a career in academic medicine and must be Board certified/eligible by the American Board of Obstetrics and Gynecology.

Fellows will be involved in teaching medical students and house officers. The fellowship program emphasizes clinical and basic research in clinical perinatology with a particular interest in ultrasound, Doppler and perinatal diagnosis. The individual will also be responsible for some general duties in obstetrics and gynecology.

Applicants should send a curriculum vitae to:

J.C. Veille, M.D.
Director, Division of Maternal-Fetal Medicine
MacDonald Hospital for Women, University Hospitals of Cleveland
2074 Abington Road
Cleveland, OH 44106
216/844-3338

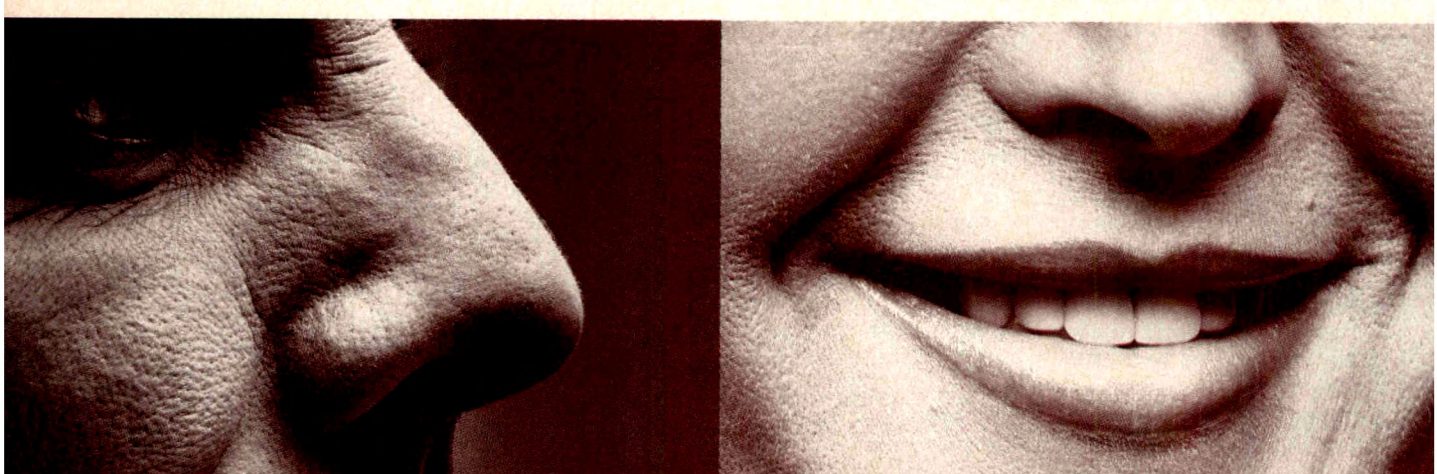
The University is an equal opportunity/affirmative action employer.

DEPARTMENT OF OBSTETRICS AND GYNECOLOGY
MEDICAL COLLEGE OF GEORGIA

** FACULTY TENURE TRACK POSITIONS IN AN EXPANDING DEPARTMENT **

(1) Maternal-Fetal Medicine position – (1) Gynecologic Oncology Position – and (2) General Obstetrics and Gynecology positions.

— Duties: patient care – teaching – research.



— Qualifications: Board pending or certified in Obstetrics and Gynecology and applicable sub-specialty.

— Rank and Salary: Open based on experience.

The Obstetrics and Gynecology Department at the Medical College of Georgia provides support and opportunity for academic advancement and professional growth. Located in Augusta, Georgia a progressive community offering a pleasant climate with an environment for quality family living. Area population 375,000.

Address inquiries with Curriculum vitae to: Donald M. Sherline, MD, Chairman, Department of Obstetrics and Gynecology, CK170, Medical College of Georgia, August, Ga. 30912.

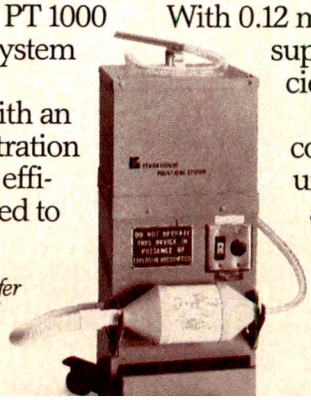
Viable DNA are lookin

Recent studies[1,2] have shown that certain types of virulent DNA have been detected intact in the plume from CO-2 lasers.



In other words, there are numerous cavities and areas where DNA can enter your body.

Now there's a safe and effective way to draw off the plume better than ever before:

The new POINT ONE™ PT 1000 Smoke Evacuation Filter System from Stackhouse.™

PT 1000 provides you with an unsurpassed final stage filtration to 0.01 micron at 99.998% efficiency. Penetration is limited to .002%.

0.01 micron filtration provides a safer environment for both the patient and the entire clinical staff.

With 0.12 micron particles, a superior 99.9995% efficiency is achieved.

A super ULPA filter, combined with a unique and highly advanced air flow design, help make it possible.

OB/GYN

Bay Shores Medical Group offers outstanding opportunities for board eligible/certified physicians to join rapidly expanding 80-physician multi-specialty group practice. Southern California community, close to ocean, easy access to city and recreational areas, excellent schools.

Please direct any inquiries and CV to:
Bradford B.Burnett, M.D.

PARTNERSHIP FOR A DRUG-FREE AMERICA

Presence of autoantibodies in women with unexplained infertility

Pamela V. Taylor, PhD, James M. Campbell, MRCOG, and James S. Scott, MD
Leeds, England

Serum samples from 41 patients suffering from unexplained infertility and 351 normal pregnant women were assayed for a range of autoantibodies by means of immunofluorescence, counterimmunoelectrophoresis, double immunodiffusion, Western blots, and enzyme-linked immunosorbent assays. The prevalence of autoantibodies to smooth muscle, phospholipid, and nuclear antigens, the latter when detected by immunofluorescence, was elevated in women with infertility compared with normal pregnant women ($p < 0.001$, <0.001, and <0.05, respectively). Antiviral antibodies were not detected. The reason for the high level of autoreactivity in infertile women is unclear, but smooth muscle and antiphospholipid antibodies may actively interfere with the reproductive process. (Am J Obstet Gynecol 1989;161:377-9.)

Key words: Autoantibodies, phospholipid antibody, infertility

The incidence of infertile couples in the general population has been estimated at 10% to 15%. In a considerable proportion of these couples, no explanation is discovered for the condition using standard techniques of investigation. In recent years various types of reproductive failure have come to be considered as having an immune component. Immunologic effects are important at many levels in the reproductive process, including fertilization, implantation, and the development of the placenta.[1] A spectrum of antibodies may be present in women during their reproductive lives either related to underlying immune disorders or as a response to paternally-derived fetal antigens. Possible effects on potential development of the embryo range from prevention of fertilization,[2] an immunoregulatory function in maintenance of the fetoplacental unit,[3] or deleterious fetal and neonatal effects caused by transport of maternal IgG across the placenta.[4] Antiphospholipid antibodies[5] and antibodies to ribonucleoprotein antigens[6] have been particularly inculpated in fetal loss, and there is preliminary evidence that autoantibody profiles can be correlated with some types of reproductive failure.[7] We have tested women suffering from unexplained infertility for a range of autoantibodies to assess the pathogenic role in this disorder.

From the Department of Obstetrics and Gynaecology, University of Leeds.
Supported by a grant from Birthright.
Received for publication October 2, 1988; revised February 1, 1989; accepted February 17, 1989.
Reprint requests: P. V. Taylor, MD, Department of Obstetrics, D Floor, Clarendon Wing, Belmont Grove, Leeds LS2 9NS, England.

Patients

Serum samples were obtained from 41 infertile patients (26 with primary and 15 with secondary infertility) and 351 normal pregnant women, mostly in the first trimester. The infertile group was investigated by laparoscopy, which revealed bilateral tubal patency and no intrapelvic bar to pregnancy. Ovulation had been confirmed by luteal phase curettage, yielding secretory endometrium, biphasic basal body temperature charts, loss of ferning in the cervical mucus, and luteal phase progesterone levels, and no abnormality had been demonstrated on seminal analysis or postcoital tests.

Methods

Serum samples were stored at −70° C and antibodies to nuclear antigens and soluble ribonucleoproteins were assayed by immunofluorescence, counterimmunoelectrophoresis, double immunodiffusion, and Western blots as previously described.[8] Antiphospholipid antibodies were detected by prolongation of the activated partial thromboplastin time and enzyme-linked immunoassay[9] with bovine heart cardiolipin (Sigma Chemical Co., St. Louis, Mo.) as the antigen. Results were considered positive in the latter when they were greater than four times the standard deviation of a mean of 100 pooled control sera. This control pool and a positive serum were included in every microtiter plate.

Smooth muscle IgG, IgM, and IgA antibodies were detected by means of indirect immunofluorescence on rodent substrates.[10] Sera from 11 infertile patients were tested for antibodies to cytomegalovirus and herpes virus and toxoplasma. Results were analyzed by the χ^2 tests with Yates' correction.

Table I. Autoantibodies to smooth muscle and nuclear and phospholipid antigens in infertile women and normal pregnant women

	Smooth muscle antibody No. positive (%)	*Antinuclear antibody No. positive (%)*	*Antiphospholipid antibody No. positive (%)*
Infertile women (n = 41)	20* (49)	4 (10)	7‡ (17)
Normal pregnant women (n = 351)	58† (17)	11 (3)	5 (6) (of 80 tested)

*All IgG; five also IgM.
†All IgG; 12 also IgM.
‡All IgG.

Table II. Values for the activated partial thromboplastin times in 41 infertile women

Patient's time/control time (seconds)

30/31*	30/32	28/27	31/30	30/27	26/27	24/27
31/30*	32/32	30/30	29/32	29/30	31/27	30/32
36/33*	24/27	31/31	30/30	35/32	31/28	36/34
25/28*	32/32	35/28	33/27	28/30	32/32	35/28
27/29*	29/31	31/30	32/31	31/29	31/31	

*Positive for IgG anticardiolipin antibody.

Results

Serologic findings with respect to smooth muscle antibody, antinuclear antibodies detected by immunofluorescence, and antiphospholipid antibodies are shown in Table I. The prevalence of these antibodies was elevated in women with infertility compared with normal pregnant women ($p < 0.001$, <0.05, and <0.001 for smooth muscle, and nuclear and phospholipid antibodies, respectively). Four of the 20 infertile women and eight of the 58 normal women who were positive for smooth muscle antibody had titers of one in 40, whereas the remainder were positive at one in 10. The seven infertile patients with IgG antiphospholipid antibody had values of 5, 8, 13, 8, 15, 7, and 7 times the standard deviation of the normal mean, respectively, for the enzyme-linked immunoassay. These values for the five normal pregnant women with IgG antiphospholipid antibody were 4, 7, 8, 9, and 12, respectively. None of the infertile patients had antibodies to ribonucleoprotein antigens, and none had prolongation of the activated partial thromboplastin time (Table II). No antiviral antibodies were detected; one patient had a positive titer for IgG but not IgM antibody to toxoplasma.

Comment

The elevated prevalences of these non-organ-specific antibodies in infertile women suggest a high level of autoreactivity in this group. Depression of immune reactivity in the control group is unlikely, since pregnancy per se seems to have no effect on the induction or suppression of antinuclear or smooth muscle antibodies[11] or antibodies to ribonucleoproteins.[8] The reported incidence of smooth muscle antibody in the normal population is in the range of 2% to 20%. Our findings of a 17% incidence associated with normal gestation agrees with those of Pietarinen et al.[12] When present in high titers, smooth muscle antibody is commonly associated with chronic active hepatitis. In low titers it is present in association with other hepatic disorders, malignancies, drug addiction, and viral infections, particularly infectious mononucleosis and cytomegalovirus. An increased prevalence of smooth muscle antibody has been reported in threatened and spontaneous abortion[12] and infertility.[13] The latter study included patients with various causes for their disorder, particularly anovulation. Persistent viral infection was suggested as a cause of both autoantibody production and infertility. We found no evidence for viral infection in the small number tested.

Prevalences of IgG antiphospholipid autoantibodies in an apparently healthy population have been reported between 1.25% and 2.25%, depending on the particular phospholipid antigen involved.[14] The presence of IgG antiphospholipid antibody has been correlated with both thrombosis and fetal death,[5] sometimes in the clinical setting of systemic lupus erythematosus but often in patients with no other abnormality. This has been designated the antiphospholipid syndrome, and our findings suggest that unexplained infertility in some patients may be associated with this syndrome. Women with unexplained infertility have a very similiar range and prevalence of autoantibody production to women suffering from spontaneous recurrent abortion.[15]

The stimulus to production of these autoantibodies

and whether they directly affect the reproductive process remain unclear. Smooth muscle antibody may reduce fertility by altering fallopian tubal function. The possibility that curettage performed as part of the infertility investigations is an etiologic factor in the production of the autoantibody requires assessment. The association between antiphospholipid antibodies and fetal loss seems to be a consequence of widespread abnormality of the uteroplacental vasculature with increased platelet aggregation, reduced blood flow, and placental infarction.[16] The mechanism of this is unclear, but the antibodies may bind to phospholipids in endothelial cell membranes and decrease prostacyclin production by blocking arachidonic acid release.[17] Such a mechanism could interefere with normal fertilization. Alternatively, if the effect is caused by the interaction at the placental site, identification of these autoantibodies in some infertile women suggests that there may be a group of such patients who suffer from undetected fetal loss rather than prevention of fertilization.

We thank Brenda Frater, Sandra Jackson, Alison Norman, and Geoffrey Tate for laboratory assistance.

Successful twin pregnancy after embryo donation to a patient with XY gonadal dysgenesis

Mark V. Sauer, MD, Rogerio A. Lobo, MD, and Richard J. Paulson, MD
Los Angeles, California

A twin pregnancy was established in a patient with XY gonadal dysgenesis. The pregnancy was supported with exogenously administered hormones for the initial 100 days. The infants were delivered by emergency cesarean section at 35 weeks' gestation when severe preeclampsia developed in the mother. (AM J OBSTET GYNECOL 1989;161:380-1.)

Key words: Gonadal dysgenesis, donor embryo transfer

Successful pregnancies in functionally agonadal women who received donated embryos have been reported.[1] Whereas most women who received donated oocytes have premature ovarian failure and normal karyotypes, one case of a singleton pregnancy in an XY gonadal dysgenesis patient has been reported.[2] We report the first twin gestation in a patient with XY gonadal dysgenesis. This case further confirms the ability of some patients with XY genotypes to carry a pregnancy when provided donated embryos.

Case report

A 28-year-old gravida 0 woman was diagnosed as having XY gonadal dysgenesis at the age of 17 years when she was first seen with primary amenorrhea. Hormonal evaluation revealed hypergonadotropic hypogonadism, and the peripheral blood karyotype was 46,XY. Gonadectomy was performed and hormonal replacement therapy was instituted.

The patient desired a child and came to us at the University of Southern California In Vitro Fertilization Program for embryo donation. She was started on hormonal replacement that consisted of oral micronized estradiol and intramuscular progesterone as previously described[1] to simulate a normal menstrual cycle. An endometrial biopsy specimen obtained on day 26 of the simulated cycle was in phase. A nonanonymous donor volunteered to undergo ovarian stimulation with human menopausal gonadotropin and human chorionic gonadotropin that preceded transvaginal ultrasonography-directed oocyte aspiration. Seven oocytes were obtained, and after incubation with the sperm of the recipient's husband, four oocytes fertilized and cleaved. Four 4-cell embryos were then transferred to the recipient's uterus by the transcervical route with a standard, 3F embryo transfer catheter on simulated cycle day 18.

Nine days after transfer the patient's serum β-human chorionic gonadotropin was 16 mIU/ml. Vaginal ultrasonography subsequently demonstrated a twin pregnancy. The patient was maintained on exogenous hormone replacement for the first 100 days' gestation at which time serum progesterone levels were confirmed to be in the normal range and medications were discontinued. At 35 weeks' gestation pregnancy-induced hypertension worsened and required delivery by emergency cesarean section. A 2955 gm male and 1477 gm female were delivered. Both infants had Apgar scores of 7 at 1 minute and 7 at 5 minutes. Discordant growth was attributed to placental insufficiency in the female. The infants did well and respiratory support was not required. The patient recovered uneventfully.

Comment

Advances in reproductive medicine have made pregnancy attainable in many patients previously considered infertile. Women with gonadal dysgenesis may achieve pregnancy by receiving embryos that developed from donated oocytes. In these and other agonadal patients, the endometrial lining responds normally to exogenous hormone replacement and becomes indistinguishable by biopsy specimen from that of women who ovulate spontaneously. This endometrium is thus receptive to embryo implantation. As illustrated by this case and those reported by others,[1, 2] if implantation occurs pregnancy progresses uneventfully and is self-sufficient after an initial period of hormonal support.

Although optimism for patients with XY gonadal dysgenesis exists, not all women with an XY genotype have this prognosis. Others may have ambiguous genitalia or functional gonadal tissue and preclude pregnancy because production of mullerian inhibiting factor in utero induces the regression of female reproductive organs. Therefore, before embryo donation, documentation of a normal uterus on hysterosalpingography is required of all potential recipients. Finally,

Ovarian hyperstimulation presenting as acute hydrothorax after in vitro fertilization

Charles R. Kingsland, MB, ChB,[a] John V. Collins, MD,[b] Botros Rizk, MB, ChB,[a] and Bridgett A. Mason, MB, BS[a]

London, England

Ovarian hyperstimulation that occurs with an isolated hydrothorax as the only symptom has previously been reported. We describe the second such case, the first to occur after in vitro fertilization and embryo transfer. (AM J OBSTET GYNECOL 1989;161:381-2.)

Key words: Ovarian hyperstimulation, isolated acute hydrothorax

Jewelewicz and Vande Wiele[1] first described a patient who had acute hydrothorax as the only symptom of ovarian hyperstimulation. In this article we report a similar case of acute hydrothorax that occurred after in vitro fertilization.

Case report

A 35-year-old woman was referred to the Bourn-Hallam Medical Centre for consideration of in vitro fertilization because of a 3-year history of primary unexplained subfertility. She had a history of recurrent chest infections but was otherwise in good health. Serum follicle-stimulating hormone concentration was 2.5 IU/L (normal range, 2.5 to 12, follicle stimulating hormone assay, AMERLEX, Amersham, England with standard second international reference preparation, 78/549) and the luteinizing hormone level was 5.3 IU/L (normal range, 5 to 20, luteinizing hormone assay, AMERLEX, Amersham, England, using standard first international reference preparation, 68/40) when taken on day 2 of the patient's cycle.

Ovarian stimulation was given in the form of clomiphene citrate (Serophene, Serono, Welwyn, England), 100 mg orally from day 2 to 6 of the menstrual cycle and human menopausal gonadotropin (Pergonal, Serono), 225 IU/L intramuscularly daily from the fourth to the ninth day of the cycle. Total urinary estrogen level rose to a maximum of 1221 nmol/24 hours. Five thousand international units of human chorionic gonadotropin (hCG, Profasi, Serono) was given intramuscularly on the tenth day of her cycle; 35 hours later ultrasonically directed oocyte recovery was performed.

Seven oocytes were retrieved. All seven were fertilized, and three were transferred via the transcervical route 72 hours after oocyte retrieval. Four embryos were frozen.

Seventy-two hours after embryo replacement, the patient complained of crampy abdominal pain. On examination, the abdomen was soft and nontender, with no evidence of ascites. An ultrasonogram showed both ovaries to be enlarged to a diameter of 5 cm. There was no evidence of free fluid. The abdominal discomfort resolved over the next 24 hours and the patient was reassured.

One week after embryo replacement, the patient was admitted to the hospital with an acute onset of dyspnea. A large right-sided hydrothorax was diagnosed clinically and was confirmed by a chest x-ray film. An ultrasonogram of the chest also showed a moderate right hydrothorax and a trace of fluid above the left hemidiaphragm. There was no ascites or evidence of pulmonary embolus. The hemoglobin value was 14.4 gm/dl, the white blood cell count was 20.2 × 10/L, and the platelets measured 761 × 10/L. Results of blood biochemistry and liver function tests were all within normal limits.

A total of 3½ L of straw-colored fluid was aspirated from the hydrothorax and had a protein count of 43 gm/L. No evidence of acid-fast bacilli was found in the

fluid with Ziehl-Neelsen staining. Cytologic and subsequent cultures of the fluid sputum and urine were negative. Results of fluorescence tests for antinuclear factor were also negative.

On the basis of these investigations, a diagnosis of hydrothorax caused by ovarian hyperstimulation was made. The patient made an uneventful recovery with no further treatment and was discharged 4 days after admission.

The patient returned to the Bourn-Hallam Centre two weeks after embryo replacement for review. She felt well and on examination had no evidence of recurrence of the effusion. A β-subunit hCG assay was performed, and the level was >25 IU/L, indicative of pregnancy. She returned home for antenatal care but miscarried at 8 weeks' gestation.

Comment

This is the second reported case of ovarian hyperstimulation that presents solely as acute hydrothorax, and is the first case to occur after in vitro fertilization. The severe form of ovarian hyperstimulation syndrome is characterized by gross ovarian enlargement, ascites, pleural effusion, and often thromboembolic phenomena that are potentially lethal conditions. In this case, although there was evidence of hemoconcentration, gross ovarian enlargement and ascites were not present either clinically or on ultrasonographic examination. Other investigations failed to reveal any other possible cause for the effusion.

Severe ovarian hyperstimulation occurs more commonly in patients who conceive after therapy. Some workers have quoted an incidence as high as 6%. However, with present methods of monitoring gonadotropin therapy, the incidence is now much lower.[2]

The pathogenesis of hyperstimulation is thought to be a transudation of fluid through the capillary basement membranes of the grossly enlarged ovaries. The absence of ascites and gross ovarian enlargement in this case leaves the mechanism by which the hydrothroax developed debatable.

Normal amniotic fluid volume changes throughout pregnancy

Robert A. Brace, PhD, and Edward J. Wolf, MD
La Jolla, California

The purpose of this study was to provide a quantitative characterization of the changes in amniotic fluid volume that occur throughout gestation. From 705 published amniotic volumes for normal pregnancies, we found that after log transformation, amniotic fluid volume had a uniform variability over 8 to 43 weeks' gestation. Thus the 95% confidence interval covered the range of 1/2.57 to 2.57 times the mean volume at any given gestational age. Contrary to expected trends, mean amniotic fluid volume did not change significantly between 22 and 39 weeks and averaged 777 ml, with the 95% confidence interval ranging from 302 to 1997 ml. The data are summarized in nomograms covering 8 to 43 weeks' gestation. (AM J OBSTET GYNECOL 1989;161:382-8.)

Key words: Amniotic fluid volume, gestational age

It is a well-recognized concept that maintenance of amniotic fluid volume within the normal range is important for promoting fetal well-being. This is because aberrations in volume either above or below normal are associated with an increased incidence of fetal and neonatal morbidity and mortality.[1, 2] A problem with this concept is that "normal" has not been defined; that is, although there have been several studies in which amniotic fluid volumes have been measured at various stages of gestation,[3-14] there has been neither an adequate characterization of the normal range of amniotic fluid volumes nor an adequate description of the variation in normal volumes with gestation. Thus the pur-

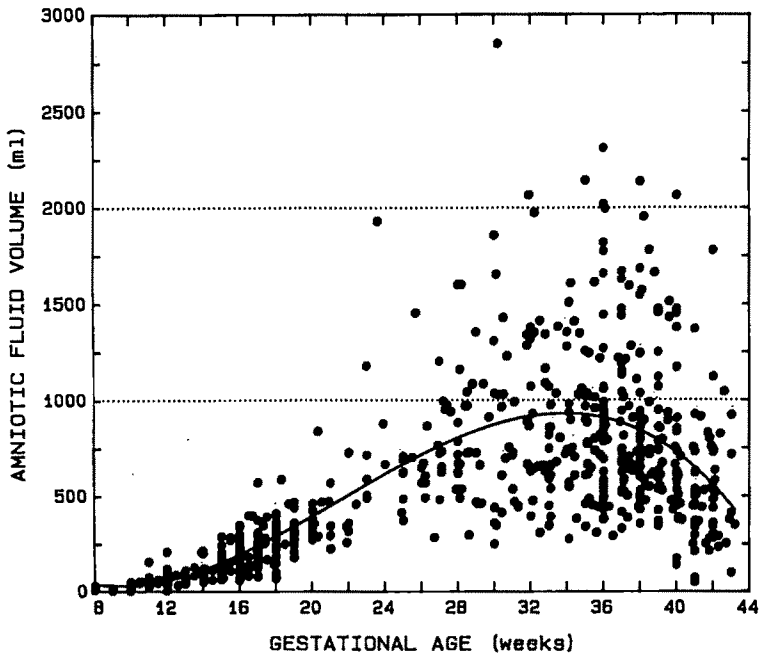

Fig. 1. Amniotic fluid volumes in human pregnancies with normal fetuses (n = 705). *Solid line* is polynomial regression line ($Y = 525.6 - 117.2X + 8.003X^2 - 0.1237X^3$, $R = 0.718$, $p < 10^{-6}$).

pose of the present study was to provide a quantitative characterization of the gestational changes in amniotic fluid volume that occur with normal pregnancies.

Methods

Paired data on amniotic fluid volume and fetal gestational age were collected from 12 previously published studies.[3-14] In these studies amniotic fluid volumes were measured either at the time of hysterotomy by direct collection,[3, 5, 6, 9, 11-14] or in continuing pregnancies by means of indicator dilution techniques.[1-8, 10, 13] For the present study, data were excluded if fetal anomalies, fetal death, spontaneous abortion, toxemia, or maternal or fetal disease were present. Thus data were included only if the fetus was considered normal. Fetuses with oligohydramnios or polyhydramnios were included if outcome was good.

The data were collected either from published tables or figures. For the latter, photographic enlargement combined with linear measurement of X-Y coordinates was used to convert points in the figures into numeric values.

Data analysis. Initially, the data are presented as the relationship between volume and age on a linear scale. For statistical analyses, amniotic fluid volumes were log transformed (base 10) because their variability was greater late in gestation than early in gestation and because the volumes at any given age were not normally distributed largely because of the presence of a few high volumes. The data were then analyzed with standard polynomial regression techniques. In addition, mean values were computed for each 2-week period (i.e., 8 to 9.99, 10 to 11.99, etc., weeks). In the figures containing 2-week averages, volumes were plotted at the computed mean age rather than at the midpoint; for example, 8.2 was the mean for the 8.0 to 9.99 week window and 38.6 was the mean for 38 to 39.99 weeks. Statistical differences in volumes among age groups were tested by means of a one-way analysis of variance with Fisher's least significant difference for multiple comparisons.[15] Variability was analyzed for the residuals calculated from the log of amniotic fluid volume minus the log as determined with the best-fit polynomial regression equation. To avoid biasing as a result of the different number of observations at each gestational age, the polynomial regression equation was determined from the means at 2-week intervals. Of 706 collected values, one volume of zero at 43 weeks was excluded from the analysis because it could not be log transformed and because there must have been at least a little fluid present.

It should be noted that it was possible to statistically define confidence intervals only for log-transformed data because volumes were not normally distributed about the mean before log transformation. To convert these into easily interpreted values, antilogs must be taken. When this is done, the confidence interval is no longer equal to the mean ± a constant but rather equals the mean multiplied and divided by a constant. For example, if the mean and 95% confidence interval were 2 ± 0.3 for the log data, the mean volume would be 100 ml (antilog of 2), with a confidence interval of

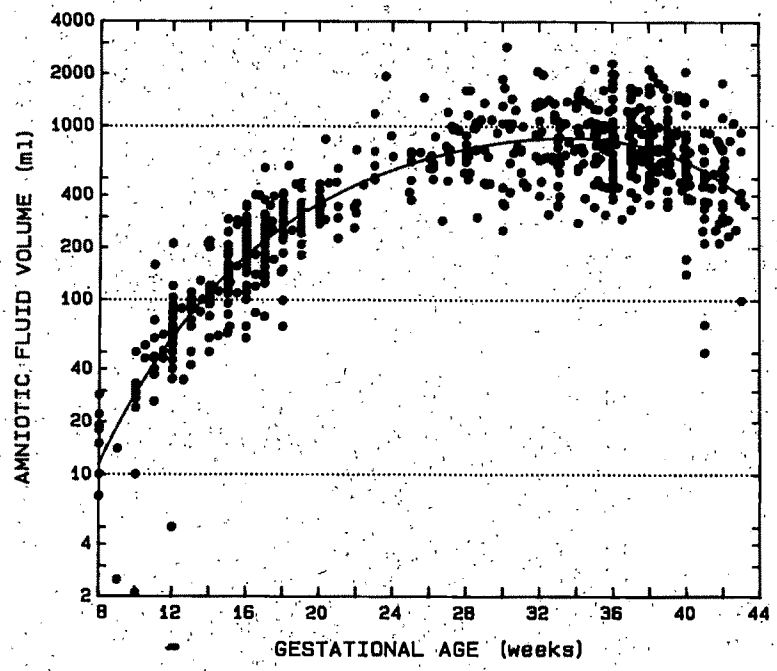

Fig. 2. Amniotic fluid volumes on a log scale in human pregnancies with normal fetuses (n = 705). *Solid line* is polynomial regression line (see text).

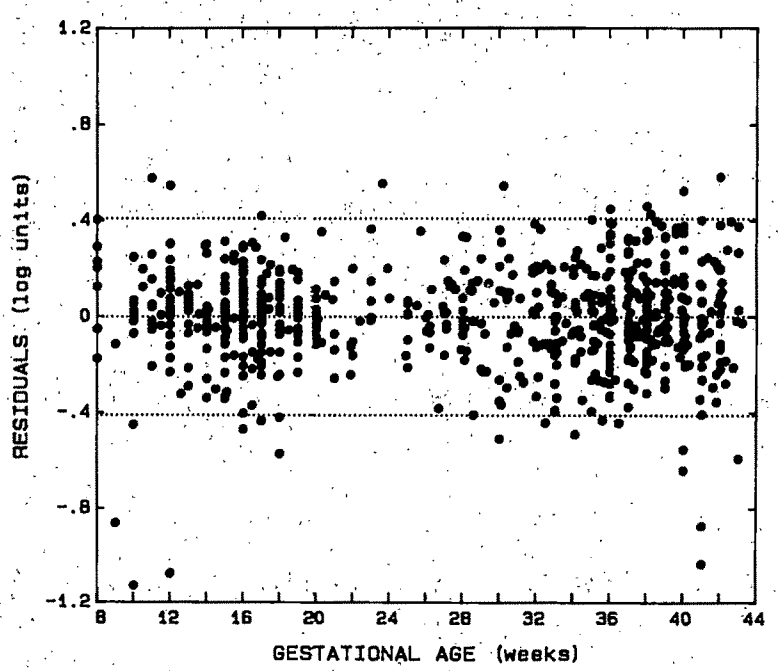

Fig. 3. Variability in amniotic fluid volumes as a function of gestational age. Data expressed as residuals calculated by subtracting value determined with polynomial regressional equation from individual points. Area between upper and lower dotted lines represents 95% confidence interval.

1/2 × 100 to 2 × 100, or 50 to 200 ml, since the antilog of 0.3 is 2.

Results

A total of 705 amniotic fluid volumes from normal fetuses were collected from 8 to 43.2 weeks' gestation. These are shown on a linear scale in Fig. 1 as a function of gestational age, along with the line of best fit as determined by polynomial regression. From the regression equation, the peak was 931 ml and occurred at 33.8 weeks.

Two major problems occur with the use of polynomial regression to describe the changes in amniotic fluid volume. First, as seen in Fig. 1, the scatter about the

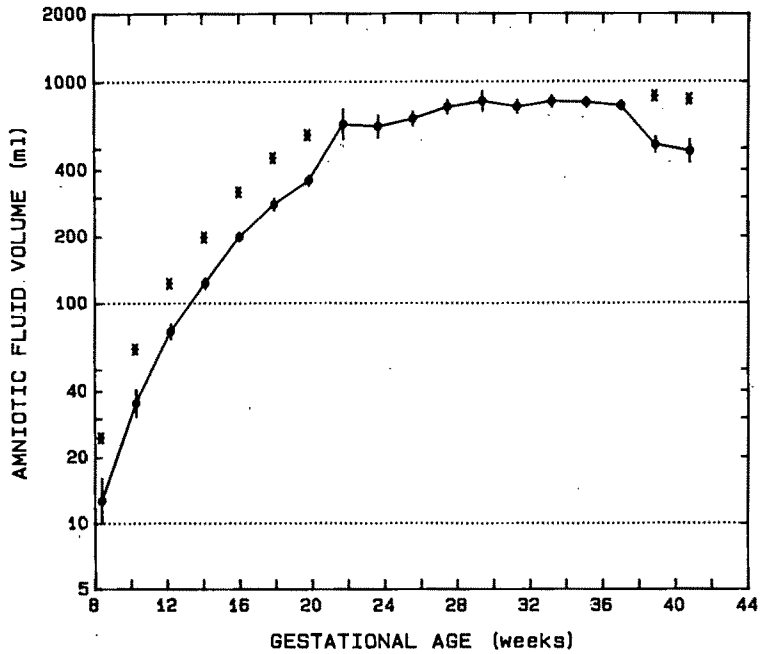

Fig. 4. Statistical analysis of gestational changes in amniotic fluid volume. Data expressed as mean ± SE for each 2-week interval. *$p < 0.0001$ compared with value at 39 weeks' gestation.

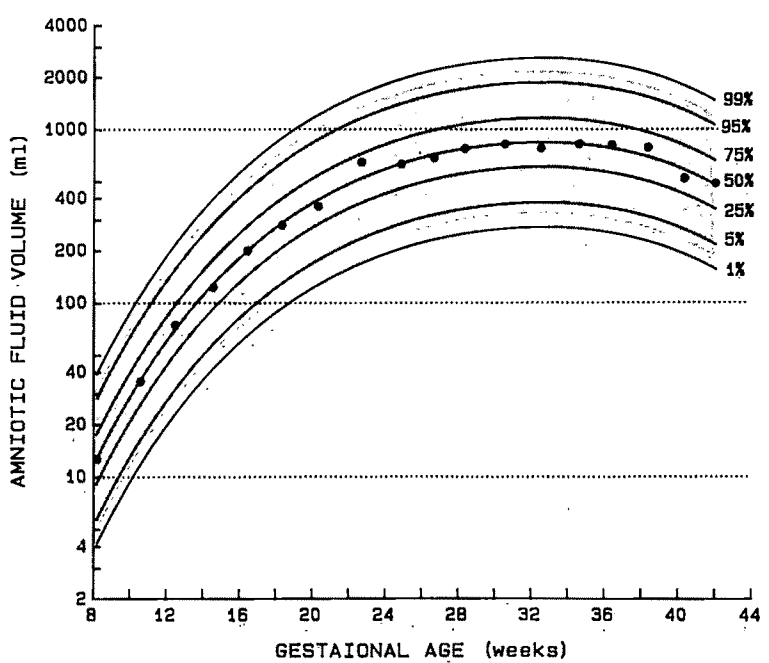

Fig. 5. Nomogram shows mean amniotic fluid volumes *(dots)* as a function of gestational age and percentiles. Volumes are plotted on a log scale. Fiftieth percentile line is polynomial regression calculated from biweekly means ($\log Y = -1.3916 + 0.4176X - 0.01622X^2 + 0.0003144X^3 - 0.0000026X^4$, $R = 0.998$, $F = 811$, $p < 10^{-6}$). *Shaded area* covers 95% confidence interval.

mean was much greater late in gestation compared with early in gestation. Thus the underlying assumption of uniform variability has been violated. Second, as readily seen in Fig. 1 at 30 to 40 weeks, the scatter above the mean (i.e., the regression line) was much greater than the scatter below the mean. Thus the assumption of a normal distribution was violated.

In an attempt to overcome these problems, amniotic fluid volumes were log transformed and are shown on a log scale in Fig. 2. Because it is difficult to visually perceive variability about a curved line, Fig. 3 replots the data of Fig. 2 after subtracting the regression line. An analysis of variance of the data in Fig. 3 found no statistically significant changes in the residuals (i.e.,

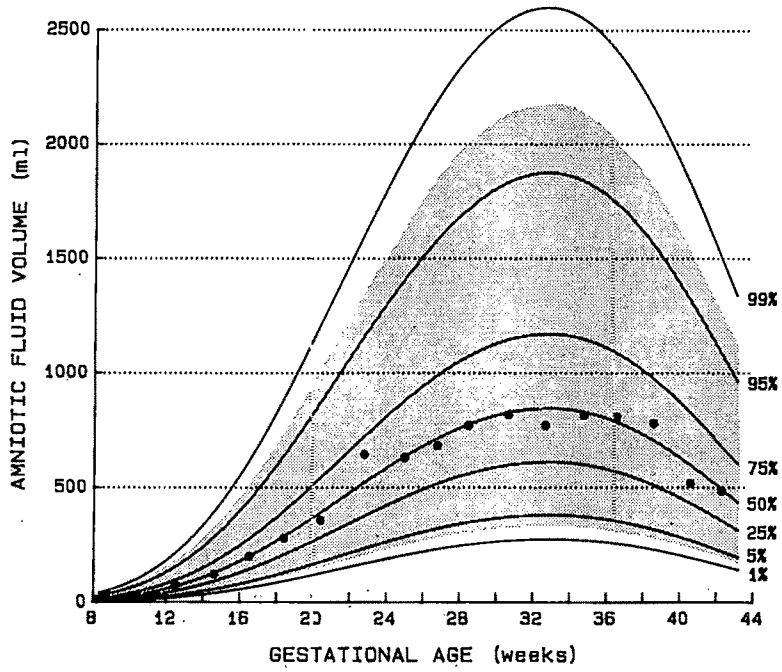

Fig. 6. Nomogram shows amniotic fluid volumes as a function of gestational age on a linear scale. *Dots* are means for each 2-week interval. Percentiles are calculated from polynomial regression equation and SD of residuals. *Shaded area* covers 95% confidence interval.

variability) with gestational age. In addition, after log transformation, amniotic fluid volumes were normally distributed about the mean for any given gestational age.

There are three major benefits of these results. First, polynomial regression now provides an adequate characterization of the changes in amniotic fluid volume with advancing gestation. When analyzed with this technique, each of the first four regression coefficients were statistically significant ($p < 0.002$). Thus the regression equation relating amniotic fluid volume (AFV) to gestational age (X) was log (AFV) = $-1.5595 + 0.4676\ X - 0.02014\ X^2 + 0.0004359\ X^3 - 0.0000039\ X^4$, with R = 0.896, F = 713, and $p < 10^{-6}$. This equation is represented by the solid line in Fig. 2.

The second benefit is that standard statistical methods can be used to compare the changes in mean volumes. As determined with an analysis of variance, the changes in amniotic fluid volume (AFV) with gestational age (Fig. 4) were highly significant (F = 160, $p < 10^{-6}$). However, there were no statistically significant changes in volume between 22 and 39 weeks' gestation; volume averaged 777 ml, and individual means ranged from 630 to 817 ml (Fig. 4).

The third benefit is that the variability of the data in Fig. 3 provides an overall estimate of the variability in amniotic fluid volume. Thus the standard deviation from the data in Fig. 3 can be used to characterize the normal range of amniotic fluid volumes throughout the range of gestational ages considered. From Fig. 3 the SD is 0.2094 so that the 95% confidence interval (1.96 X SD) is 0.4105 (log units). This means that 95% of all women with a normal fetus have amniotic fluid volumes within the range of 1/2.57 to 2.57 times, or within 39% to 257% of the mean volume for any gestational age over 8 to 43 weeks' gestation (2.57 is the antilog of 0.4105).

Nomograms showing the changes in amniotic fluid volume as a function of gestational age are shown in Fig. 5. As can be seen, these were calculated by adding or subtracting various multiples of the overall SD of the residuals to the mean volume calculated from the polynomial regression equation (i.e., the fiftieth percentile). The shaded area covers the 95% confidence interval (i.e., the 2.5 to 97.5 percentiles). These same data are replotted on a linear scale in Fig. 6 to facilitate comparisons.

The mean changes in amniotic fluid volume calculated on a weekly basis (from the polynomial regression equation) are shown in Fig. 7. At 8 weeks, volume is increasing at 10 ml/week. This increases to 25 ml/week at 13 weeks and reaches a maximum of 60 ml/week at 21 weeks' gestation. The weekly volume increment then decreases and reaches zero at 33 weeks' gestation, that is, volume is at maximum at this time. In contrast to this pattern, the weekly volume change when expressed relative to total volume decreases throughout weeks 8 to 43 of gestation (dashed line in Fig. 7). Thus mean amniotic fluid volume is increasing 45% per week at 8 weeks, 25% per week at 15 weeks, 10% per week at 24

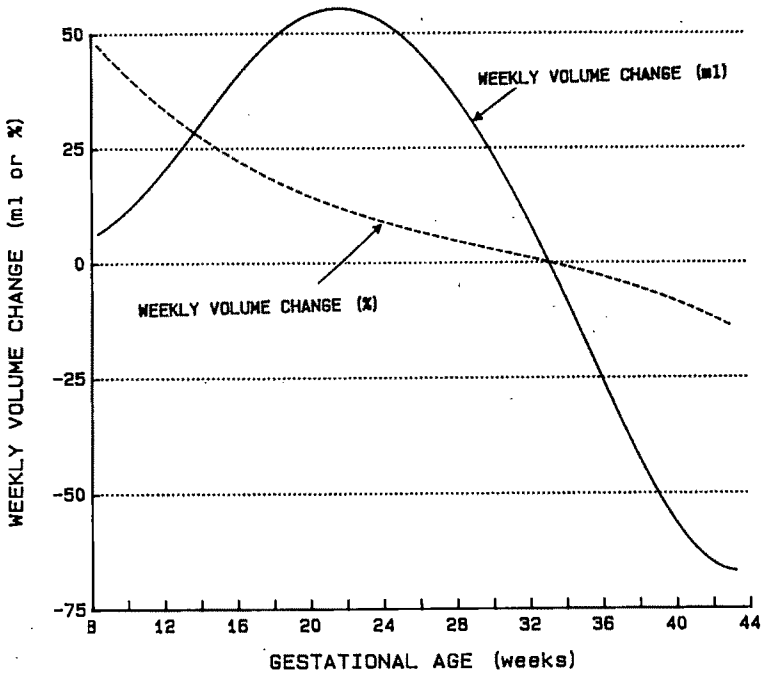

Fig. 7. Weekly changes in mean amniotic fluid volume as calculated from best-fit polynomial regression equation.

weeks, and 0% at 33 weeks. At 40 weeks, volume is decreasing an average of 8% per week.

Comment

The major significance of this study is that we were able to statistically characterize for the first time normal amniotic fluid volumes over the last 80% of gestation. This also provides a statistical definition of abnormal amniotic fluid volumes so that limits can be set for oligohydramnios and polyhydramnios. For example, as seen in Figs. 5 and 6, at 30 weeks' gestation, the 95% confidence interval about the mean (817 ml) covers the range of 318 to 2100 ml. Thus with <318 ml of fluid oligohydramnios would be present and with more than 2100 ml polyhydramnios would be present. Each of these occur 2.5% of the time.

Another observation is that after a progressive rise from 8 weeks' gestation, amniotic fluid volume reaches its statistical maximum at 22 weeks' gestation and remains at this level (630 to 817 ml) through 39 weeks' gestation, declining thereafter. Although Fuchs[16] had reported that mean amniotic fluid volume was relatively constant during the last trimester, it has been more widely accepted that amniotic fluid volume reached a peak at 34 weeks' gestation and declined thereafter.[10] This difference is largely attributable to the different methods of averaging (absolute values versus logs) in the studies; that is, a few cases of hydramnios had biased the mean value upward at 34 weeks' gestation. In addition, a statistical analysis of the volume changes with time was not performed in the previous studies so that these two statements are not necessarily inconsistent with each other. This same contradiction arises in the present study in that the analysis of variance revealed no significant changes in volume between 22 and 39 weeks (Fig. 4). On the other hand, the mean volume as determined from the regression equation reached its peak at 33 weeks and declined thereafter, which is in agreement with Queenan et al.[10] In this case, the polynomial regression equation most likely provides a better estimate of the trends in amniotic fluid volume. Thus with a much larger data set, a peak around 33 weeks' gestation would be more easily identified.

A final new observation is that from 8 to 43 weeks' gestation, the variability in amniotic fluid volume about the mean is constant when expressed as log-transformed data. Thus 95% of the time amniotic fluid volume will be within the range of 1/2.57 to 2.57 times the mean volume at any given gestational age. At present we do not know why the variability is constant, but it probably relates to the volume regulatory mechanisms. It also should be noted that this variability is quite large. Factors, such as maternal age, gravidity and parity, and ethnicity and race, may have contributed to the variability, but we were unable to explore these factors because they were absent from the original reports.

In summary, this study provides a statistical characterization of the changes in amniotic fluid volume that occur in normal human pregnancy. This also provides

a definition of oligohydramnios and polyhydramnios over 8 to 43 weeks' gestation.

Doppler velocimetry and placental disease

Luis A. Bracero, MD, Debra Beneck, MD, Nancy Kirshenbaum, MD, Marianne Peiffer, RDMS, Patricia Stalter, CDMS, and Harold Schulman, MD

Valhalla and Mineola, New York

Quantitative placental examinations were performed on 47 women who had Doppler flow velocity studies of the umbilical artery during their pregnancy. The systolic-diastolic ratio of the umbilical artery was used as the measurement parameter to divide the study population into two groups. Group 1 consisted of women with normal systolic-diastolic ratios (systolic-diastolic < 3), and group 2 consisted of women with an elevated systolic-diastolic ratio (systolic-diastolic ≥ 3). The group with an increase in systolic-diastolic ratio had more perinatal complications as demonstrated by two stillbirths, a higher incidence of cesarean deliveries for fetal distress, and more admissions to the neonatal intensive care unit. Significant differences were found when gestational age at delivery, placental weight, birth weight, and the number of small muscular arteries in the placenta were compared. Since gestational age may have accounted for the difference in placental findings, patients were matched for gestational age. The placental weights were comparable, but there were fewer small muscular arteries in those patients with an increase in systolic-diastolic ratio ($p < 0.001$). In addition, when these findings were examined to determine the influence of diminished uterine flow velocity, none was found. (AM J OBSTET GYNECOL 1989;161:388-93.)

Key words: Umbilical artery velocity waveforms, Doppler ultrasound, placenta

Umbilical artery velocity waveform analysis has been proposed as a new placental function test. It has been reported that an umbilical artery systolic-diastolic ratio of <3 during the third trimester implies normal placental function, whereas a systolic-diastolic ratio ≥ than 3 implies a strong probability of abnormal outcome.[1] These outcomes include small-for-gestational age fe-

tuses, poorly controlled diabetes, discordant twins, low Apgar scores, trisomy 13 and 18, cesarean section for fetal distress, and more admissions to the neonatal intensive care unit.[2-5] Previous studies have suggested a correlation between umbilical artery velocity waveforms and placental morphology.[6,7] The purpose of this study was to confirm and expand these observations to understand better the significance of an elevated systolic-diastolic ratio.

Material and methods

Forty-seven women who had Doppler flow velocity studies of the umbilical artery during pregnancy had quantitative placental examinations. There were various indications for performing umbilical artery Doppler flow velocity studies (Table I). A continuous-wave Doppler ultrasound scan with a 4 MHz transducer, a power density of 6.5 mW/cM^2, and a spectrum analyzer were used to identify and measure velocity waveforms. When the umbilical artery signal is obtained, it is freeze-framed and a systolic peak-to-diastolic trough ratio is calculated. Four separate fields of waveforms are measured, and an average systolic-diastolic ratio is calculated for each examination. In addition, we studied the velocity waveform of the uterine artery to determine if maternal circulation influences placental findings. This is done by placing the ultrasound transducer on the abdomen on the right and left paracervical areas. The uterine artery has a distinct contour that allows it to be easily differentiated from the other pelvic vessels. A systolic-to-diastolic ratio was obtained for each uterine artery, and these measurements were then averaged. One set of measurements was obtained at each examination. A uterine artery systolic-diastolic ratio >2.6 after 26 weeks is considered abnormal.[8] The systolic-diastolic ratio of the umbilical and uterine arteries obtained during the last examination before delivery was used for statistical analysis.

The study population was divided into two groups. Group 1 was made up of 29 women with normal umbilical artery systolic-diastolic ratios (systolic-diastolic < 3). Group 2 consisted of 18 women with an elevated umbilical systolic-diastolic ratio (systolic-diastolic ≥ 3). A two-tailed *t* test for independent samples or a two-tailed paired *t* test was used to test differences between the normal and abnormal systolic-diastolic ratio groups for all interval variables. A two-tailed χ^2 was used to test for differences in categoric variables, such as admissions to the neonatal intensive care unit and cesarean section deliveries for fetal distress. In addition, a multivariate analysis of variance was performed on the data, holding the arterial count as the dependent variable. The statistical package SPSS/PC+ was used for all statistical analysis.

The methodology for the study of the placenta is similar to that described by Giles et al.[6] and McCowan et al.[7] The placentas were weighed fresh, with cord and membranes attached, and then immediately fixed in 10% formalin for at least 1 day. After adequate fixation, longitudinal cuts through the maternal surface were made at approximately 2 cm intervals. At least two blocks were prepared from each placenta, one from an area 2 cm from the insertion of the cord and another from an area 2 cm from the disk margin. Areas of obvious infarction were avoided, and additional sections were submitted in cases in which there was extensive infarction. The paraffin-embedded tissue was cut and then stained with hematoxylin and eosin for preliminary evaluation, followed by Masson trichrome, for better demonstration of the vascular musculature and surrounding collagen.

Five fields at × 100 magnification were scanned from each block by one pathologist, who was unaware of the results of the umbilical artery velocity waveform. Subchorionic and basal areas and areas of infarction were avoided, as were artifactually distorted areas. Tertiary stem villi and small muscular arteries were counted in each field. Small muscular arteries were defined as vessels with a diameter between 20 and 90 μm and with a muscular coat greater than a single cell in thickness.[6] Vessel diameter was measured as the greatest external transverse diameter in a section at right angles to the line of the vessel. A micrometer disk (Bausch & Lomb, Rochester, N.Y.), calibrated at × 100 was used to obtain this measurement. The results are reported as the total number of tertiary stem villi and small muscular arteries counted in the 10 fields studied in each placenta.

Results

The mean systolic-diastolic ratio for group 1 was 2.5 ± 0.4 and 4.0 ± 0.9 for group 2. Five patients in group 2 had absent end-diastolic velocity. When gestational age at delivery, placental weight, birth weight, and number of small muscular arteries were compared, statistically significant differences were found between

these two groups (Table II). Newborn infants from patients in group 2 had lower 1-minute Apgar scores (group 1 = 7 ± 2.6; group 2 = 5 ± 3.2; two-tailed *t* test, $p = 0.017$). This group had two antepartum fetal deaths because of abruptio placentae. The incidence of cesarean deliveries performed for fetal distress was 55% in group 2 and 10% in group 1 ($p < 0.001$). Seventy-eight percent of the newborns delivered to patients in group 2 required admission to the neonatal intensive care unit versus 38% of the newborns delivered to patients in group 1 ($p < 0.01$).

The data were corrected for gestational age (Table III) because this variable may have accounted for the significant differences seen between groups 1 and 2. The only difference that remained significant was in the number of small muscular arteries. This difference can be seen in a sample of a placenta from a patient with a normal ratio (Fig. 1) and that of a patient with an abnormal ratio (Fig. 2).

The most abnormal umbilical artery velocity waveform is that in which there is no end-diastolic velocity. We compared those patients with elevated umbilical systolic-diastolic ratios to those with absent end-diastolic velocity and found no significant differences in the number of small muscular arteries. The group with absent end-diastolic velocity tended to deliver earlier (29 ± 2.7 versus 34 ± 3.4 weeks; two-tailed *t* test, $p = 0.006$), have lower birth weight infants (776 ± 242

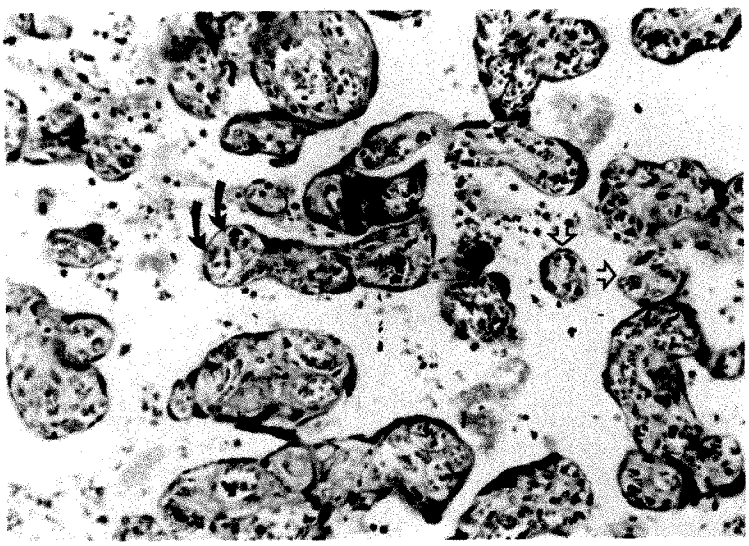

Fig. 1. Placental photomicrograph of patient with systolic-diastolic ratio of 2.4. Note abundance of well-vascularized terminal villi *(open arrows)*. Tertiary stem villi contain abundant small muscular arteries *(curved arrows)*. (Original magnification ×200; Masson trichrome.)

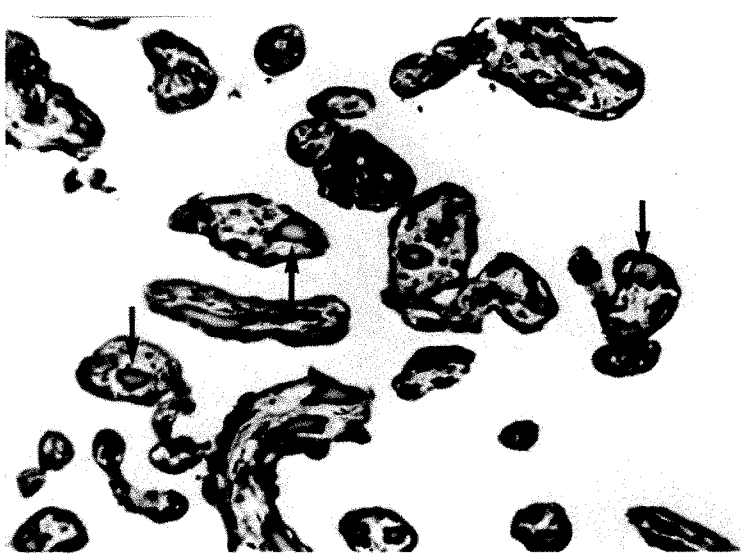

Fig. 2. Placental photomicrograph of patient with absent end-diastolic velocity. Poorly vascularized tertiary stem villi with few capillaries *(straight arrows)*. There is a lack of small muscular ateries in this field, which is representative of the vascular condition of this placenta. (Original magnification, ×200; Masson trichrome.)

versus 1950 ± 783 gm; two-tailed *t* test, $p = 0.0005$), and smaller placentas (244 ± 90 versus 431 ± 133 gm; two-tailed *t* test, $p = 0.01$).

To determine if the difference seen in the arterial count could be accounted for by one disease process or could only be identified by the systolic-diastolic ratio of the umbilical artery, we independently compared those patients with diabetes, preeclampsia, chronic hypertension, and preterm labor with the members of our study population without these conditions. No significant differences were found in the number of tertiary stem villi or the number of small muscular arteries in any of these groups.

The patient population was also divided on the basis of the systolic-diastolic ratio value of the uterine arteries (Table IV) to see if uterine flow affected placental histologic findings. Women who had an elevated systolic-diastolic ratio of the uterine artery had higher umbilical artery velocity waveform systolic-diastolic ratios than those with normal uterine artery systolic-diastolic ratios. There was no significant difference in the placental weight, number of tertiary stem villi, or number of

Table V. Arterial count (mean ± SD) in the four vascular patterns obtained with Doppler ultrasound studies

	Normal umbilical	*Abnormal umbilical*	*p value*
Normal uterine	82 ± 26 (n = 24)	44 ± 13 (n = 11)	$p < 0.001$*
Abnormal uterine	77 ± 21 (n = 5)	48 ± 31 (n = 7)	$p = 0.06$

*The p value denotes a two-tailed t test for independent samples.

small muscular arteries. Next, women with abnormal velocity waveform systolic-diastolic ratios of the umbilical artery were subdivided according to the uterine systolic-diastolic ratio. Again, there were no significant differences in the number of tertiary stem villi or small muscular arteries. The four possible combinations of vascular patterns obtained with Doppler ultrasound examination are analyzed with regard to the number of small muscular arteries seen in the placenta (Table V). The data suggest that uterine flow was not a critical factor in the development of the small muscular arteries.

Comment

Giles et al.[6] performed placental examinations in patients who underwent Doppler flow velocity studies before delivery. They found that there was a decrease in the number of small muscular arteries in those patients with elevated systolic-diastolic ratios of the umbilical artery. In the group with abnormal systolic-diastolic ratios, placental weights were significantly lower than those of patients with normal systolic-diastolic ratios. There also was a disproportionately large number of intrauterine growth-retarded newborn infants in the group with abnormal systolic-diastolic ratios. The fact that they studied smaller placentas and smaller infants in the abnormal systolic-diastolic ratio group may account for the decrease seen in the number of small muscular arteries.

McGowan et al.[7] have performed a similar study with a smaller patient population and used the pulsatility index as the measure of umbilical artery velocimetry. They found a decrease in the number of small muscular arteries in those patients with a high pulsatility index. In their study corrections were not made for gestational age (31 weeks in the high pulsatility index group versus 37 weeks in the low pulsatility index group) or for birth weight (1053 gm in the high pulsatility index group versus 3054 gm in the low pulsatility index group). Again, these significant differences between the two groups could account for the differences seen in the number of small muscular arteries.

The purpose of our study was to try and correct for all variables that could theoretically influence the small muscular arterial count, since clinically we find that the group with elevated systolic-diastolic ratios has preterm deliveries, smaller placentas, and smaller newborn infants. After correcting for the encountered variables, we could then compare the two groups whose only difference was in the systolic-diastolic ratio value (Table III). Our findings suggest that in this group the increase in the systolic-diastolic ratio is associated with a decrease in the number of small muscular arteries within the placental vascular tree. This decrease in the number of vessels appears to be independent of gestational age, birth weight, placental weight, disease process complicating pregnancy, and uterine artery flow velocity (multivariate analysis of variance, $p > 0.05$).

Giles et al. hypothesized that the decrease in the number of placental vessels is caused by an obliterative process. They based this opinion on two observations. First, they saw that as pregnancy progressed, the systolic-diastolic ratio became higher in pregnancies, resulting in growth-retarded newborns. Second, they saw collections of nuclear material in some abnormal placentas, which they believed represented obliteration of a small artery. However, we observed systolic-diastolic ratios that decreased as pregnancy progressed, although they still remained in the abnormal range. We also saw obliteration of vessels in placentas with both normal and abnormal systolic-diastolic ratios. This finding was seen in a small number of placentas and cannot be used to make a general statement. It is possible that this vessel obliteration may represent a normal aging process in some placentas, but our data on vessel number between 33 and 36 weeks show no differences. Furthermore, Giles et al. demonstrated that the average small muscular arterial count increases slightly with gestational age in those patients with normal and abnormal systolic-diastolic ratios of the umbilical artery. Thus the decrease in the number of vessels in the abnormal umbilical artery group must occur at a much earlier period of gestation. Vascular resistance occurs primarily across the arterioles. If there are diminished arterioles with no change in the radii of the remaining vessels, it would still not be clear whether velocity would be affected because of the net diminution in area (velocity = flow/area). The associated elevated systolic-diastolic ratio indicates that velocity is diminished. Since most ancillary studies on umbilical vein flow in intrauterine growth-retarded newborns indicate a reduced volume of blood flow,[9] it can be hypothesized that in most of these cases there is a developmental arrest of placental angiogenesis. The stimuli for angiogenesis are un-

known, but these data suggest that successful therapy would have to be carried out early in the second trimester of pregnancy because an unchanging pattern emerges by 25 weeks.

This is the third study demonstrating an inverse relationship between an elevated umbilical artery systolic-diastolic ratio and the small muscular arterial count of the stem villi. Since these findings occurred in varying clinical situations (hypertension, diabetes, lupus erythematosus, etc.), it appears that the decrease in arterial counts is a response that could be initiated by varying stimuli.

Local methotrexate injection: A nonsurgical treatment of ectopic pregnancy

Mordechai Pansky, MD, Ian Bukovsky, MD, Abraham Golan, MD, Rami Langer, MD, David Schneider, MD, Shlomo Arieli, MD, and Eliahu Caspi, MD

Zerifin, Israel

Twenty seven patients with unruptured tubal pregnancy were selected for nonsurgical treatment with the use of one injection of 12.5 mg of methotrexate into the ectopic site at laparoscopy. No adverse reactions were observed. In three patients (11%), a laparotomy was performed because of rising β–human chorionic gonadotropin titers. In the other patients, serum β–human chorionic gonadotropin levels decreased to the nonpregnant range with no further intervention, and the patients recovered uneventfully. This method is suggested as an alternative to surgery in selected cases of early unruptured tubal pregnancy. (AM J OBSTET GYNECOL 1989;161:393-6.)

Key words: Local methotrexate, tubal pregnancy

Surgical removal of the tube or products of conception has been the treatment of choice for tubal pregnancy. However, postoperative morbidity exists, and the procedure requires as long as 6 days of hospitalization and 4 to 6 weeks of recovery. It has recently been shown that surgery can be avoided in carefully selected cases.[1, 2] Future fertility after nonoperative management seems to be better than after conventional surgery.[3]

Methotrexate, a cytotoxic drug that is largely used in cases of gestational trophablastic disease,[4] had previously shown promise in resolving unruptured ectopic pregnancies when given systemically, thereby eliminating the need for surgery.[2, 5, 6] However, its systemic use exposes the patients to serious side effects and toxicity. To minimize the risk of these side effects and maximize benefit from high tissue concentrations of methotrexate in the fallopian tube, the drug was locally applied by one injection to the pregnancy site at laparoscopy.

We present our experience with treating unruptured tubal pregnancy by a local methotrexate injection at laparoscopy.

Material and methods

Of the 73 ectopic pregnancies diagnosed at the Assaf Harofe Medical Centre during 1988, 70 were tubal. A diagnosis of ectopic pregnancy was made clinically and supported by (β–human chorionic gonadotropin) levels and ultrasonography. Final confirmation of the diagnosis and selection of treatment were made at laparoscopy. The following selection criteria were used: (1) The largest diameter of the tubal pregnancy did not exceed 3 cm; (2) the tubal serosa was intact and no active bleeding could be observed; and (3) the pelvis could be fully visualized.

Informed consent was obtained from each patient before laparoscopy after detailed explanation. Twenty-seven (38%) of the 70 cases of tubal pregnancy, which were diagnosed from January to December 1988, fulfilled the selection criteria.

After meticulous screening of the whole pelvis, the involved tube was grasped by an atraumatic forceps through a second puncture. Methotrexate, 12.5 mg, diluted in 2 ml of physiologic solution, was injected into the pregnancy site through the tubal wall by means of a 15 cm long spinal needle (18 gauge) introduced under laparoscopic guidance. Each patient was carefully observed for changes in pulse, blood pressure, and other vital signs for the first 48 hours. Daily serum β–human chorionic gonadotropin levels were determined after surgery. Patients remained in the hospital until β–human chorionic gonadotropin levels fell on 2 consecutive days or reached the level of 10 mIU/ml. Thereafter each patient was seen every 24 to 48 hours on an ambulatory basis, clinically examined, and serum β–human chorionic gonadotropin levels determined. Follow-up was terminated when β–human chorionic gonadotropin level dropped below 10 mIU/ml.

Results

Patient characteristics and clinical data are summarized in Table I. Ages ranged from 22 to 42 years (mean, 30 years). Mean gestational age of the group was 46 days with a range of 35 to 60 days. Range of serum β–human chorionic gonadotropin on admission was 55 to 1860 mIU/ml. The location of tubal pregnancy was ampullary in all patients: 20 on the right and seven on the left. All 27 patients underwent the procedure without any adverse reaction. Twenty-four patients were discharged 2 to 5 days later because of decreasing serum β–human chorionic gonadotropin levels.

Three patients (cases 2, 8, and 19) required a laparotomy because of a further rise in β–human chorionic gonadotropin levels. In the first two cases serum β–human chorionic gonadotropin levels dropped during the first 2 to 3 days after the injection, indicating an initially promising response. Although both women were asymptomatic and clinically stable, laparotomy was performed on days 8 and 5, respectively. The third patient (case 19) had a continuous rising serum β–

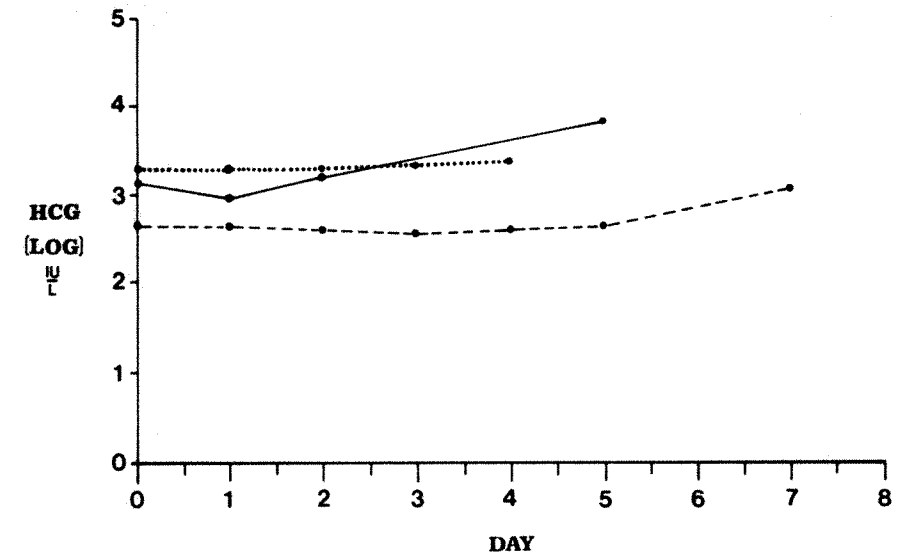

Fig. 1. β–Human chorionic gonadotropin levels of three patients requiring salpingectomy.

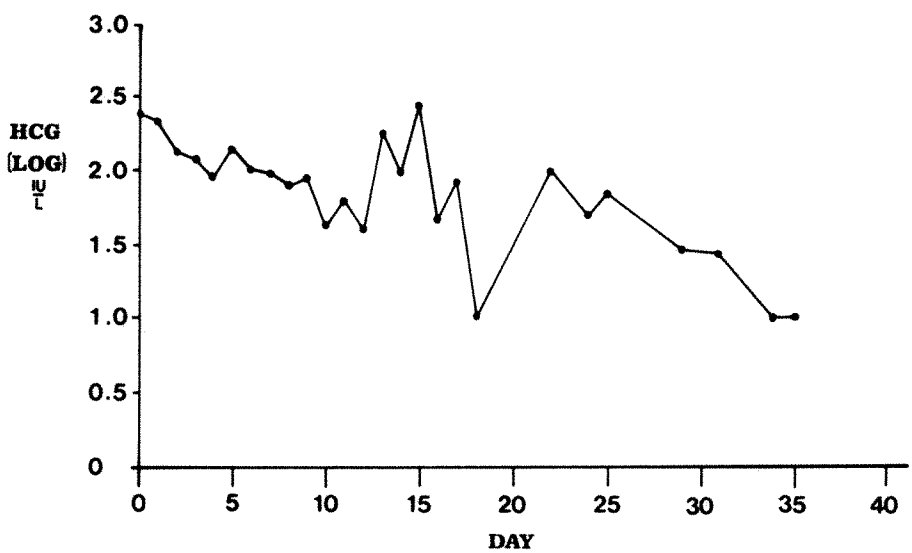

Fig. 2. β–Human chorionic gonadotropin levels (average) of 24 patients not having surgery.

human chorionic gonadotropin pattern and an acute onset of severe abdominal pain on the fourth day after the injection and immediately had surgery.

In all three failures, an unruptured tubal pregnancy was found, with no blood in the peritoneal cavity (not even in the latter case) and salpingectomy was performed. The β–human chorionic gonadotropin patterns for the three failures are presented in Fig. 1. Three patients requested tubal sterilization, which was performed by electrocautery after injection of methotrexate.

The pattern and average levels of serum β–human chorionic gonadotropin for the successful cases are presented in Fig. 2. In two patients it took as long as 34 and 35 days for hCG levels to drop to 10 mIU/ml. The average for all patients was 12 days. None of the treated patients had any adverse reactions related to methotrexate.

Hospitalization averaged 4 days (range, 2 to 11 days). So far seven patients have had postoperative hysterosalpingography, which showed normal patency of the affected tube in six and distal occlusion in the seventh patient.

Three patients conceived again; one is an ongoing normal intrauterine pregnancy. One had an early induced abortion and one an early spontaneous abortion.

Comment

The introduction of various new diagnostic measures, such as rapid β–human chorionic gonadotropin assays and vaginal ultrasonography, has significantly expedited the diagnosis of ectopic pregnancy. More

and more tubal pregnancies are diagnosed early in an unruptured state.[7]

Methotrexate had proved to be well suited for the eradication of trophoblastic tissue in ectopic locations.[5, 6, 8] Ory et al.[8] reports on six patients with ampullary ectopic pregnancies treated with intravenous methotrexate followed by leucoverin. Only one patient required laparotomy, and two received blood transfusions. Ichinoe et al.[9] report a 95.7% success rate with systemic methotrexate alone, showing high rates of patency of the affected tube.

Sauer et al.[2] expanded the series of Ory et al.[8] and report high success rate by treating tubal pregnancies with systemic methotrexate in combination with citrovorum factor.

However, with systemic administration of methotrexate toxicity is expected as many as 20% to 30% of patients.[2, 8, 9] An increased incidence of congenital anomalies in subsequent pregnancies was also reported.[10]

Recently nine cases of unruptured tubal pregnancy were successfully treated with laparoscopy by local injection of prostaglandin $F_{2\alpha}$.[11]

Use of local injection of methotrexate under laparoscopic control enabled us to avoid abdominal surgery in 24 of 27 (89%) patients and thus reduce postoperative recovery time. Applied in this manner methotrexate probably achieves higher tissue concentration in the affected tube, thereby avoiding the systemic route and thus reducing the risk of adverse reactions and side effects.

Our three failures may be related to technical problems, such as leakage of the injected methotrexate through the injection site or an additional puncture in the posterior wall of the tube, which could be responsible for the failures. In such a case, an additional dose of methotrexate can be given. We used a fixed dose of methotrexate for all patients. Since two of these three patients had the highest preoperative β–human chorionic gonadotropin levels, perhaps a higher dose is necessary in such cases.

We believe and suggest that this mode of treatment provides a safe and relatively effective alternative to surgery in patients with early unruptured tubal pregnancy. It is very tempting to be able to establish an alternative to surgery in ectopic pregnancies. Hospital stay is shortened and surgical risks and complications are avoided. Such an alternative should be acceptable if the incidence of side effects and complications remains low. It seems that the suggested protocol conforms with such demands.

Make researching easier with the Ten-Year Cumulative Index (1978-1987) to the American Journal of Obstetrics and Gynecology

The Ten-Year Cumulative Index is a complete guide to more than 30,000 pages of original articles, case reports, letters, and editorials published in the American Journal of Obstetrics and Gynecology from 1978 through 1987 (volumes 130 to 157). Numbering more than 800 pages, the Cumulative Index includes both a subject and an author index. This hard-cover volume is $64.50 ($69.00 international). Prices include shipping. *Payment must accompany all orders and must be in U.S. funds, drawn on a U.S. bank.*

Contact The C.V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146 USA; phone (314) 872-8370, ext. 394. In the U.S., call toll-free: 1-800-325-4177, ext. 394. Please allow six weeks for delivery.

Serial human chorionic gonadotropin determinations by fluoroimmunoassay for differentiation between intrauterine and ectopic gestation

Bo Lindblom, MD, PhD, Mats Hahlin, MD, and Peter Sjöblom, PhD

Göteborg, Sweden

A new means for differentiation between ectopic and early intrauterine pregnancy—the human chorionic gonadotropin score—is described. The score relates the rate of serum hCG rise per day to the initial human chorionic gonadotropin level. The positive predictive value for ectopic pregnancy was 94.7%, based on human chorionic gonadotropin scores from 41 women with increasing human chorionic gonadotropin levels in the range of 10 to 4000 IU/L. The method may be useful for identification of ectopic pregnancy in a category of women in whom ultrasonography is of limited diagnostic value. (Am J Obstet Gynecol 1989;161:397-400.)

Key words: Human chorionic gonadotropin, ectopic pregnancy, fluoroimmunoassay, diagnosis

Ectopic pregnancy can lead to massive intraabdominal bleeding; the danger increases with the gestational length.[1] Early recognition of ectopic pregnancy reduces the risk of medical emergency and makes it possible to use conservative therapy (e.g., laparoscopic surgery)[2] and medical treatment.[3, 4]

The proportion of cases that are seen early in the course of ectopic pregnancy is increasing in our population, probably as a result of a better knowledge among clinicians with regard to risk determinants[5, 6] and possibly also an increasing awareness among patients about ectopic pregnancy. Since ultrasonography is of limited diagnostic value in very early pregnancy,[7, 8] we have considered the use of serial human chorionic gonadotropin (hCG) assays as a single diagnostic tool in patients with "low" hCG levels (i.e., <4000 IU/L).

As in intrauterine pregnancy, the serum levels of hCG in ectopic pregnancy are related to the gestational length but the levels of hCG are usually lower.[9] Consequently, the mean rate of hCG increase in serum, the hCG slope, is lower in ectopic pregnancy.[7, 10]

Thus serial determination of hCG in early pregnancy can be used as a single tool to distinguish pathologic gestation from viable intrauterine pregnancies.[7, 10] However, these methods did not account for the fact that the hCG increase is not linear.[11, 12] The purpose of our study was to develop an improved method for early recognition of ectopic pregnancies that takes into account the nonlinear hCG increase.

Material and methods

Serum hCG levels were determined in 181 women admitted to the hospital for suspicion of ectopic pregnancy. Many of these patients were asymptomatic, but because of anamnestic factors such as previous ectopic pregnancy or a history of infertility were considered at high risk for developing ectopic pregnancy.[6] The initial hCG value was <10 IU/L in 51 of these 181 women; these subjects were considered nonpregnant. Twenty-eight cases had initial hCG values >4000 IU/L and were excluded from further hormonal analyses and alternatively had ultrasonographic examination. Sixty of the remaining 102 women with initial hCG values of between 10 and 4000 IU/L had decreasing levels, excluding a viable pregnancy. The majority of the latter cases had curettage and, in cases of suspected ectopic pregnancy, diagnostic laparoscopy. The remaining 42 women had an initial hCG value of 10 to 4000 IU/L with rising levels and thus constituted a diagnostic problem. These women were carefully monitored clinically to establish the final diagnosis. One single case was excluded from further analysis because the diagnosis could not be settled.

The criteria for the diagnosis of normal intrauterine pregnancy (n = 22) were normal fetal development, including heart activity in the eighth gestational week, studied by endovaginal ultrasonography (Brüel and Kjaer, Naerum, Denmark). The diagnosis of ectopic

hCG values in international units per liter. Day 0 is initial value.

pregnancy (n = 19) was based on laparoscopy, in the majority of cases followed by laparotomy. Regardless of the operative method (laparoscopy or laparotomy), the presence of extrauterine trophoblast was confirmed by histopathologic examination. Information about the last menstrual bleeding is often misleading in patients with pathologic pregnancies because of spotting and for this reason we made no evaluation of gestational length.

hCG determinations. Blood sera, stored at −20° C for up to 7 days, were analyzed for hCG by the time-resolved fluoroimmunoassay described by Pettersson et al.[18] This nonisotopic immunoassay method involves a double antibody reaction with the second antibody labeled with europium. The sensitivity of the assay is approximately 0.5 IU/L; the upper limit for quantitation without dilution is approximately 8000 IU/L. Assay kits were purchased from Pharmacia Diagnostics, Sweden. The intraassay coefficient of variation was 5%. The interassay coefficient of variation was 8% (at 10 to 10,000 IU/L). The crossreactivity against human luteinizing hormone was less than 0.5%.

Computations and statistics. For each patient, the two hCG values were used in calculation of the slope of hCG rise.

The absolute slope was defined as the difference be-

tween the final and the preceding ("initial") readings, divided by the time interval (days) between the sample collection: Absolute slope = final hCG − initial hCG/sample interval.

The relative slope of hCG rise was defined as the difference between the final and the initial hCG values divided by the initial value and the time interval (days) between the sample collection: Relative slope = final hCG − initial hCG/initial hCG × sample interval.

The hCG score is the data point obtained by plotting the initial hCG value against its corresponding absolute slope. To separate the two categories of patients (intrauterine or ectopic pregnancy), a discriminatory curve was drawn betwen the two clusters of data points.

The Mann-Whitney U test was used for statistical comparisons. A p value <0.05 was considered significant.

Results

The hCG readings for each of the patients are shown in Table I, which also includes the absolute and relative slopes for each patient. The 41 patients were ranked according to the value of the relative slope. The medians of the initial values for the two groups of patients were not significantly different. Conversely, the medians of both the absolute and relative slope differed significantly (Table I).

By use of the absolute slope to differentiate between normal intrauterine pregnancy and ectopic pregnancy, an hCG rise of 285 IU/L/day was found to give the best discrimination. Thus 95.4% (21 of 22) of normal intrauterine pregnancies had slopes above this limit, whereas 84.2% (16 of 19) of ectopic pregnancies showed an hCG rise below this value (Table I).

Similarly, at a discriminatory level of 0.19, the relative slope had a positive predictive value for normal intrauterine pregnancies and ectopic pregnancies of 95.4% (21 to 22) and 84.2% (16 to 19), respectively.

Fig. 1 shows both the hCG score and the discriminatory function for each patient. The equation of the discriminatory function was: $y = 12.31 \cdot x^{0.46}$, where y is the absolute slope and x is the initial hCG value. Twenty-one of the 22 intrauterine pregnancies had val-

ues above the discriminatory curve, whereas one was below. Of the ectopic pregnancies, 18 of 19 had values below the line and one above. Thus the positive predictive value for intrauterine pregnancy in the case of an hCG score above the discriminatory curve was 95.4%. Values below the discriminatory curve had a positive predictive value for ectopic pregnancy of 94.7%.

The positive predictive values of the three methods of analyzing hCG data are summarized in Table II. The two cases incorrectly classified by the hCG score were also incorrectly classified by the other two methods (Table III).

Comment

Compared with the absolute and relative slopes of hCG increase, the hCG score appears to give better discrimination between early viable intrauterine pregnancies and ectopic pregnancies. The hCG score seems to be of specific value for identification of ectopic pregnancies with relatively rapid rise in hCG values (case 13, 14, 18, 19). This is of particular interest because such ectopic pregnancies generally are associated with a dramatic clinical presentation, including a high risk of tubal rupture and massive intraabdominal bleeding.

Abdominal ultraasonographic examination has a great documented value for differentiation of pregnancies when hCG values are >6500 IU/L.[7] With an endovaginal ultrasonographic transducer, good accuracy is achieved at still lower hCG levels[8, 14]; we arbitrarily chose an upper limit of 4000 IU/L for the initial hCG value.

No spontaneous abortions were encountered in this group of early pregnancies. This is explained by the exclusion of all cases with falling hCG titers, although it is realized that a small proportion of miscarriages may occur with rising hCG levels for limited periods of time.[12]

When the sample interval is extended, an increasing number of ectopic pregnancies will exhibit a subnormal hCG rise and, hence, an hCG score below the discriminatory curve. Although extension of the interval provides better differentiation, this delays the recognition of ectopic pregnancies with the associated risks for acute hemorrhage. In our opinion, the sampling interval should be in the range of 1 to 2 days. Shorter sample intervals may be less reliable because of the normal fluctuation of the serum hCG concentration and the assay variability.

One of the 19 ectopic pregnancy cases could not be correctly classified as such with the discriminatory curve chosen. If the discriminatory curve was moved upward to include this woman, four instead of one woman with normal intrauterine pregnancies would have been incorrectly classified. Not surprisingly, an increased sensitivity thus implies a reduced specificity. This phenomenon is even more pronounced when the absolute and relative slopes are used.

We conclude that the hCG score appears to give clinically useful information to diagnose ectopic pregnancy in a group of women in whom ultrasonography is of limited diagnostic value.

Dandy-Walker syndrome: A review of fifteen cases evaluated by prenatal sonography

Paul D. Russ, MD,[a] Dolores H. Pretorius, MD,[b] and Mark J. Johnson, MD[c]

Denver, Colorado, San Diego, California, and Columbus, Ohio

Fifteen cases of the Dandy-Walker syndrome evaluated by prenatal sonography were reviewed retrospectively. A posterior fossa cyst communicating with the fourth ventricle was a feature in each case. Hydrocephalus was present in 53% of fetuses. Extracranial congenital malformations were documented in 60% of cases. Cardiac, genitourinary, gastrointestinal, and skeletal anomalies were noted. Of 12 available karyotypes, 4 (33%) were abnormal, including two cases of trisomy 18. Excluding terminated pregnancies, there was an overall mortality of 55%. Associated congenital defects contributed to 83% of the postnatal deaths. The Dandy-Walker syndrome can be accurately diagnosed in utero by sonographic demonstration of characteristic morphologic changes in the fetal posterior fossa. The prenatal examination should include an evaluation of associated supratentorial and extracranial defects. Coexisting structural and chromosomal anomalies occur frequently and adversely affect survival. (Am J Obstet Gynecol 1989;161:401-6.)

Key words: Fetus, ultrasonographic studies, central nervous system, Dandy-Walker syndrome

The Dandy-Walker syndrome is a congenital brain malformation involving the fourth ventricle and cerebellum.[1, 2] Cystic dilatation of the fourth ventricle is associated with aplasia or hypoplasia of the cerebellar vermis.[1, 3-5] Obstructive hydrocephalus is a common feature.[3, 4, 6]

The Dandy-Walker syndrome is estimated to complicate approximately one in 25,000 to 35,000 pregnancies.[6] The usefulness of prenatal sonography in the detection and diagnosis of the Dandy-Walker syndrome has been demonstrated.[1, 2, 5, 7, 8-10] We present 15 cases of the Dandy-Walker syndrome evaluated by sonography in utero. The purposes of this study were to further examine prenatal sonographic findings, to describe related intracranial and extracranial anomalies, and to review obstetric and neonatal outcome.

Material and methods

Fifteen fetuses with the Dandy-Walker syndrome were evaluated by prenatal sonography in our departments from 1980 through 1987. Sonograms and medical records were reviewed retrospectively. If several sonographic examinations had been performed during the pregnancy, data were compiled from the first available study. Subsequent scans were evaluated for significant longitudinal changes.

Sonograms were reviewed for fetal gestational age in menstrual weeks as determined by measurements of femur length and abdominal circumference. Biparietal diameter and head circumference measurements were noted. Head circumference measurements were compared with normal values compiled by Jeanty and Romero,[11] and macrocephaly was diagnosed if the head circumference exceeded the 95th percentile. The fetal posterior fossa was analyzed for features of the Dandy-Walker malformation, including: (1) a central cyst communicating with the fourth ventricle, (2) agenesis or dysgenesis of the vermis, and (3) splaying of the cerebellar hemispheres with anterolateral displacement against the tentorium (Fig. 1, *A* and *B*). The midline anteroposterior dimension of the posterior fossa cyst was measured from axial images (Fig. 1, *A*). Hydrocephalus and other intracranial structural abnormalities were noted (Fig. 1, *C*). Ventriculomegaly was graded subjectively as normal, mild, moderate, or severe. Extracranial congenital anomalies were recorded. Amniotic fluid volume was assessed subjectively as decreased (oligohydramnios), normal, or increased (polyhydramnios).

Maternal records were evaluated to establish the following: (1) the reason for sonography, (2) gestational age at delivery, and (3) mode of delivery. The clinical outcome was determined in each case. Autopsy reports and neonatal medical records were reviewed for confirmation of the Dandy-Walker syndrome. Associated structural and chromosomal anomalies were noted.

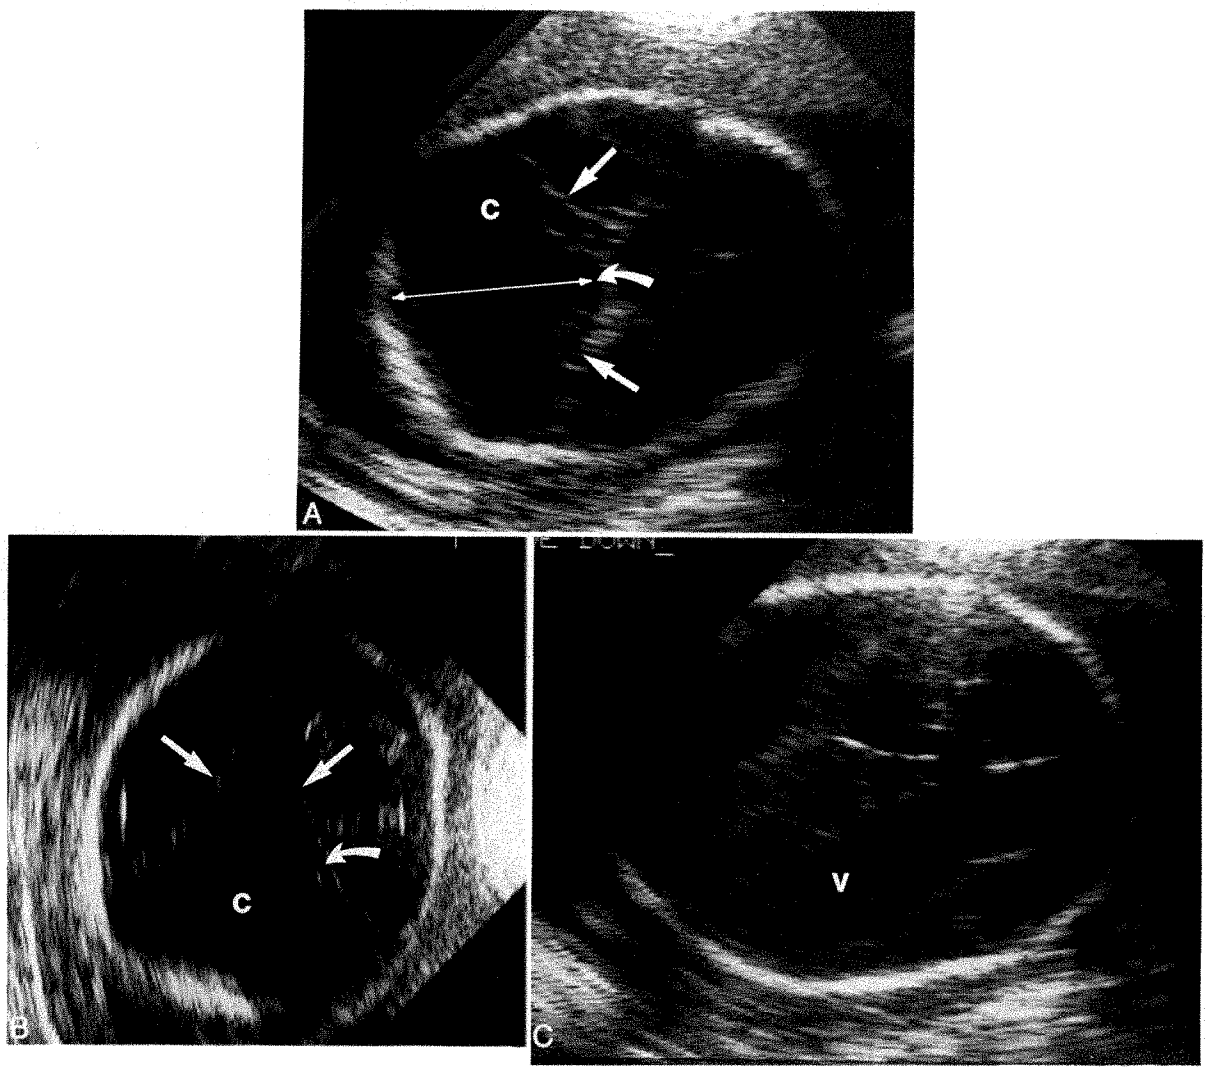

Fig. 1. Prenatal sonogram demonstrates intracranial features of Dandy-Walker syndrome in 28-week fetus. **A,** Axial scan through posterior fossa shows large cyst *(C)* communicating with fourth ventricle through defect of vermis *(curved arrow)*. Hypoplastic cerebellar hemispheres are anterolaterally displaced against tentorium *(straight arrows)*. Sagittal anteroposterior dimension of cyst *(double arrow)* measures 44 mm. **B,** Coronal scan through posterior fossa shows symmetric triangular Dandy-Walker cyst *(C)* and elevation of tentorium *(straight arrows)*. Note one of the rudimentary cerebellar hemispheres adjacent to tentorium *(curved arrow)*. **C,** Axial scan through cerebral hemispheres demonstrates moderate hydrocephalus with dilatation of the lateral ventricles *(V)*. Upside ventricle is obscured by artifact.

Results

Initial sonograms had been obtained for the following indications: size-dates discrepancy ($n = 6$), previous child with the Dandy-Walker syndrome ($n = 3$), premature labor ($n = 1$), premature rupture of membranes ($n = 1$), and routine gestational dating ($n = 1$). The reason for the initial scan was unknown in three cases. At the time of referral, the gestational age determined by sonography ranged from 22 to 36 weeks.

Posterior fossa morphologic features consistent with the Dandy-Walker syndrome were identified at the time of referral in 14 of 15 cases (93%). In one fetus with mild hydrocephalus at 24 weeks' gestation, the cerebellum and posterior fossa appeared normal, but a follow-up sonogram obtained 10 weeks later demonstrated features of the Dandy-Walker malformation (Fig. 2).

The anteroposterior dimension of the posterior fossa cyst ranged from 7 to 45 mm. This measurement was >10 mm in 14 of 15 cases (93%) at the time of referral. The single exception occurred in the fetus with a posterior fossa that appeared normal at initial examination. In this case the corresponding measurement was 7 mm at presentation, but as gestation pro-

gressed, it exceeded 10 mm before the vermian defect could be detected.

Ventriculomegaly was present in 8 of 15 fetuses (53%) and was graded as mild (n = 4), moderate (n = 2), or severe (n = 2). Macrocephaly was present in 3 of 15 fetuses (20%). In 4 fetuses, enlargement of the Dandy-Walker cyst and worsening hydrocephalus was documented by serial sonograms.

Oligohydramnios complicated 4 of 15 pregnancies (27%), including one case of premature rupture of the membranes. Polyhydramnios was present in 4 of 15 pregnancies (27%). Amniotic fluid volume was normal in 7 of 15 cases (46%).

Elective abortion was done in 3 pregnancies. An induced vaginal delivery with cephalocentesis performed in 1 case resulted in a stillbirth. The gestational age at delivery of nonterminated pregnancies ranged from 27 to 41 weeks. Eleven live births resulted from 3 vaginal deliveries and 8 cesarean sections.

There were 6 subsequent deaths among the 11 live births corresponding to a mortality rate of 55%. Five of the six deaths (83%) were secondary to coexisting extracranial congenital anomalies, whereas one postnatal death (17%) resulted from neurologic sequelae of the Dandy-Walker syndrome. Three neonatal deaths occurred within 5 days of delivery, whereas three infants died between 5 and 24 months of age.

Five survivors have been followed up from 2 to 60 months. Treatment has included neurosurgical shunting in 4 of these cases. Neurologic development has ranged from normal to severely delayed among the survivors.

Intracranial abnormalities occurring in conjunction with the Dandy-Walker syndrome noted at prenatal sonography, autopsy, or neonatal evaluation are listed in Table I. Extracranial malformations were documented in 9 of 15 cases (60%) and are summarized in Table II. Four of twelve available karyotypes (33%) are abnormal. Chromosomal anomalies included 2 cases of trisomy 18, a partial 11q trisomy, and an interstitial deletion of chromosome 2.

Comment

The pathogenesis of the Dandy-Walker syndrome was originally postulated to be congenital atresia of the foramina of Magendie and Luschka with obstructive hydrocephalus predominantly affecting the fourth ventricle.[12] Subsequent experimental and clinicopathologic studies suggested that the Dandy-Walker syndrome represents a complex developmental anomaly of the rhombencephalon rather than the sequelae of foraminal obstruction.[3, 4, 9, 13] Because of associated facial, cardiac, and limb anomalies, it has been suggested that the Dandy-Walker malformation originates before the sixth or seventh week of embryonic development.[4, 6, 14]

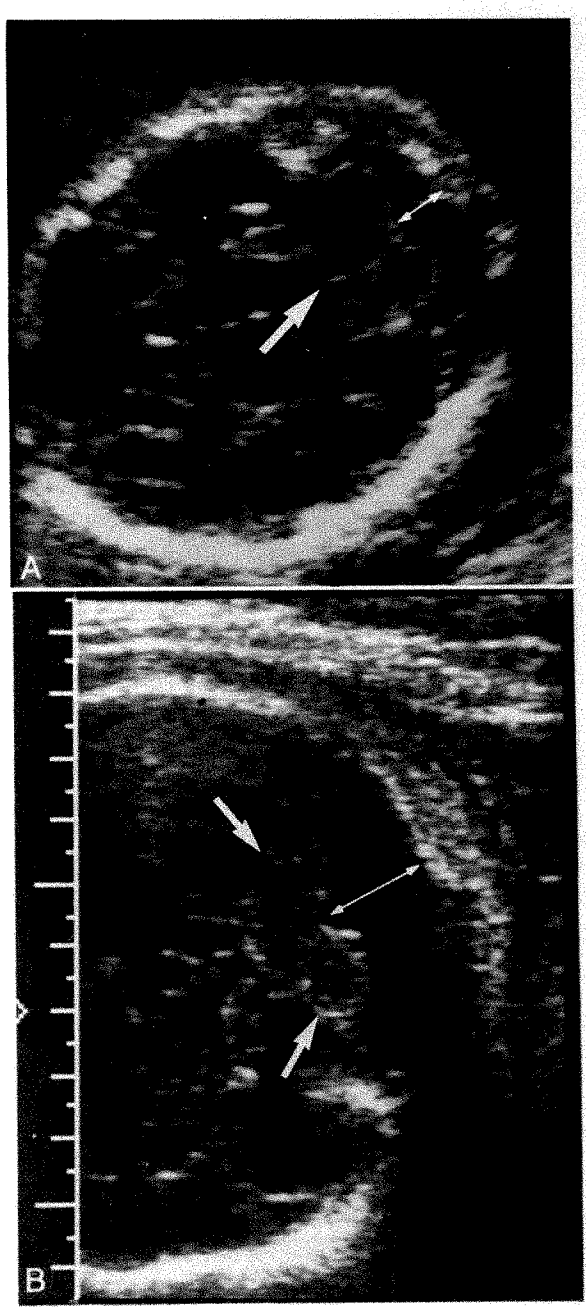

Fig. 2. Progressive morphologic changes in fetus with Dandy-Walker syndrome. **A,** Axial scan at level of cerebellum *(straight arrow)* demonstrates normal-appearing posterior fossa at 24 weeks' gestation. Sagittal depth of retrocerebellar fluid *(double arrow)* measures 7 mm and does not indicate presence of a cyst. **B,** Axial scan at 34 weeks demonstrates mild splaying of hypoplastic cerebellar hemispheres *(straight arrows)*. Abnormal midline measurement *(double arrow)* of 19 mm helps to confirm presence of posterior fossa cyst.

The prenatal diagnosis of the Dandy-Walker syndrome depends on the demonstration of a posterior fossa cyst communicating with the fourth ventricle through a defect of the cerebellar vermis (Fig. 1, *A*).[9] Although present from very early in gestation,[4, 6, 14]

small vermian defects can be difficult to detect in utero.[9] Additional findings variably manifested in the posterior fossa include separation, anterolateral displacement, and hypoplasia of the cerebellar hemispheres (Fig. 1, *A*), elevation of the torcula and tentorium (Fig. 1, *B*), and enlargement of the occiput.[1, 2, 7, 9, 12]

In our study posterior fossa abnormalities characteristic of the Dandy-Walker syndrome were noted in all cases. The spectrum of morphologic changes ranged from a subtle vermian defect to massive cystic dilatation of the fourth ventricle with minimal remnants of cerebellar tissue. In one fetus with hydrocephalus, the posterior fossa anatomy appeared normal at 24 weeks' gestation, but typical findings of the Dandy-Walker syndrome became apparent over the next 10 weeks of follow-up (Fig. 2).

Although hydrocephalus is usually described as a feature of the Dandy-Walker syndrome, it is not invariably present.[2, 4, 6] Hydrocephalus was demonstrated in only 53% of our cases. Comparable observations have been made by others. Pilu et al.[9] observed enlarged ventricles in 3 of 5 fetuses (60%) with the Dandy-Walker syndrome examined in utero, whereas Nyberg et al.[10] noted ventriculomegaly in 71% of 7 fetuses evaluated by prenatal sonography.

As noted by others [2, 4, 7, 15], the degree of ventricular dilatation can be variable among cases of the Dandy-Walker syndrome. In our study ventriculomegaly ranged from mild enlargement of only the third ventricle to severe dilatation of the lateral ventricles with pronounced thinning of the cerebral mantle. In one fetus with gross hydrocephalus, associated aqueductal stenosis was confirmed at autopsy. Macrocephaly was noted to correlate with moderate to severe ventriculomegaly.

The differential diagnosis of the Dandy-Walker syndrome includes retrocerebellar arachnoid cyst and prominent fetal cisterna magna.[7, 9, 13, 16] Because the normal depth of the fetal cisterna magna does not exceed 10 mm, measuring the sagittal dimension of a suspected posterior fossa cyst helps to establish the presence of an abnormality.[16] Unlike the Dandy-Walker malformation, arachnoid cyst and large cisterna magna are not associated with a vermian defect or other intrinsic cerebellar or cerebral abnormality.[1, 13, 16] Retrocerebellar arachnoid cysts can compress but do not communicate with the fourth ventricle.[7, 13, 15] Whereas a Dandy-Walker cyst is seen as a triangular midline fluid collection with symmetric splaying of the cerebellar hemispheres (Fig. 1, *B*), an arachnoid cyst can be asymmetrically positioned in the posterior fossa and tends to be rounded.[7, 15] Although these features can aid in diagnosis, the sonographic differentiation between the Dandy-Walker syndrome and a retrocerebellar arachnoid cyst can be difficult.[5, 7]

The Dandy-Walker syndrome has been associated with additional brain abnormalities in approximately 68% of cases.[4] These include aqueductal stenosis, gyral anomalies, heterotopias, and malformations of inferior olivary and dentate nuclei.[4, 12] Agenesis of the corpus callosum has been reported in 7% to 17% of cases.[4, 6, 15] Instances of the Dandy-Walker syndrome occurring with holoprosencephaly, occipital meningocele, and encephalocele have been described.[6, 9, 13, 15] In our study a variety of intracranial anomalies were documented (Table I), including agenesis of the corpus callosum in 4 cases.

Extracranial congenital anomalies have been associated with Dandy-Walker syndrome in approximately 25% of cases.[4] Facial abnormalities that have been reported include dysmorphism, cleft palate, and hemangioma.[4, 6, 9, 10] Congenital heart lesions that have been described include ventricular septal defect, patent foramen ovale, patent ductus arteriosus, pulmonary stenosis, pulmonary atresia, and coarctation.[6, 9, 14, 15, 17] More complex cardiac malformations have occurred, such as tetralogy of Fallot, Ebstein anomaly, hypoplastic right ventricle, transposition with single ventricle, and cor biloculare.[10, 14, 17] Associated skeletal abnormalities

have included polydactyly, syndactyly, vertebral segmentation anomalies, and lethal short-limbed dwarfism.[4, 6, 14, 17] Bowel malrotation, Meckel diverticulum, and urogenital malformations have occurred sporadically.[4, 12, 15, 17]

Extracranial structural anomalies were present in 60% of the fetuses that we studied. Cardiac, genitourinary, gastrointestinal, facial, and skeletal malformations were noted (Table II). Fetal echocardiography detected the double-outlet right ventricle and the atrioventricular canal. Obstructive uropathy secondary to urethral stenosis or abnormal external genitalia occurred in 3 fetuses. Oligohydramnios and pulmonary hypoplasia contributed to neonatal death in two of these cases.

The frequency of chromosomal defects in the Dandy-Walker syndrome is uncertain.[10] Hirsch et al.[6] noted two cases of trisomy 21 and one abnormality of chromosome 5, in their review of 40 pediatric patients. Nyberg et al.[10] reported one trisomy 18 and one mosaic trisomy 13 among 4 cases with chromosomal analysis. In our series 33% of 12 available karyotypes were abnormal, including 2 cases of trisomy 18, a partial 11q trisomy, and an interstitial deletion of chromosome 2. Although central nervous system malformations are uncommon in trisomy 18,[18] the Dandy-Walker syndrome has been associated with this chromosomal duplication syndrome.[10, 19]

Familial recurrences of the Dandy-Walker syndrome are infrequent. Although 3 of our cases had previously affected siblings, Murray et al.[19] have estimated the prevalence of the Dandy-Walker syndrome among sibs to be 2%. Hirsch et al.[6] reported only six instances of familial clustering among 300 cases compiled from the literature. Although not considered a hereditary disorder,[6] the Dandy-Walker syndrome can be a manifestation of certain autosomal recessive and X-linked dominant syndromes.[19] Excluding these disorders, the recurrence risk for the Dandy-Walker syndrome in subsequent pregnancies is approximately 1% to 5%.[19]

The natural history of the Dandy-Walker syndrome is not well known.[9, 10] As noted in this report and by others,[5, 7, 9] enlargement of the posterior fossa cyst and worsening hydrocephalus can be observed in utero. Since progressive changes are often slow, conservative management is usually possible.[8] However, severe or rapidly increasing ventriculomegaly can necessitate aggressive obstetric intervention.[9, 20] Of the cases not detected prenatally, 80% to 85% will present before 1 year of age with symptoms of hydrocephalus.[6, 15]

Overall mortality rates of 12% to 50% have been reported for the Dandy-Walker syndrome in the pediatric neurosurgical literature.[6] A mortality rate of 55% was noted for nonterminated pregnancies in our study. Excluding elective abortion, Nyberg et al.[10] documented a mortality of 67%. Fetal and neonatal deaths are often attributable to extracranial malformations.[10, 15] Associated congenital anomalies contributed to 83% of postnatal deaths among our cases.

The functional outcome for survivors is variable. Subnormal intelligence (IQ < 83) is manifested in 41% to 71%.[6, 15] More severe intellectual impairment has been observed in cases of agenesis of the corpus callosum.[15]

In conclusion, the Dandy-Walker syndrome can be diagnosed accurately with prenatal sonography by demonstrating a posterior fossa cyst communicating with the fourth ventricle through a defect of the cerebellar vermis.[9, 10] There is great variability of intracranial findings in fetuses with the Dandy-Walker syndrome. A sagittal measurement exceeding 10 mm helps to confirm the presence of a Dandy-Walker cyst. The sonographic examination, including fetal echocardiography, should be directed toward identifying additional supratentorial and extracranial anomalies. Follow-up sonograms are useful for monitoring cyst size and ventriculomegaly. Fetal karyotyping is recommended for chromosomal analysis.[9, 10, 19] The presence of multiple congenital defects adversely affects survival.

The frequency and management of uterine perforations during first-trimester abortions

Steven G. Kaali, MD, Ivan A. Szigetvari, MD, PhD, and George S. Bartfai, MD, PhD
Dobbs Ferry, New York

The frequency and management of uterine perforation during first-trimester abortions remain a matter of continuing debate among gynecologists. The rate of uterine perforations was 1.3/1000 procedures (eight cases) in 6408 women undergoing first-trimester abortions at our clinic. We also performed 706 first-trimester abortions at the time of laparoscopic sterilization. Two perforations (2.8/1000 procedures) were reported before laparoscopy. Twelve (15.6/1000 procedures) unsuspected perforations were discovered during direct laparoscopic visualization. This represents a 19.8/1000 procedure rate of perforation (14 cases). All 22 patients with perforations were managed conservatively, and no immediate or late complications were noted. Our data suggest that the true incidence of uterine perforations is significantly underestimated and serious complications caused by perforations are rare. Conservative therapy is recommended rather than early surgical intervention. (Am J Obstet Gynecol 1989;161:406-8.)

Key words: Abortion, uterine perforation, management

First-trimester abortion is a simple and commonly performed procedure. However, complications, including uterine perforations, occur. The incidence of uterine perforation varies between 0.8 and 6.4/1000 procedures.[1, 2]

Uterine perforations are usually diagnosed as a result of physician suspicion. Definite diagnosis can be made on rare occasions when abdominal contents are brought out through the cervix or invading instruments reach beyond the uterine cavity. According to Mittal and Misra,[3] unrecognized perforations are rather common, and the true incidence of uterine perforations is underestimated without direct pelvic visualization. White et al.[4] described 19 unsuspected uterine perforations during 624 laparoscopic sterilizations, making the frequency 30/1000 procedures. Similar conclusions were reached by Chi and Feldblum[5] during 20,000 laparoscopic and minilaparotomy sterilizations.

The frequency of and therapy for uterine perforations remain a matter of continuing debate among gynecologists. This propective study describes our experiences with the rate of recognized and unsuspected uterine perforations and their management.

Material and methods

Between Jan. 1, 1986, and Dec. 31, 1987, 6408 first-trimester abortions, including termination of three molar gestations, were performed by vacuum aspiration at our free-standing surgical facility. The average age of the patients was 21 years, and parity was 0.7 in this study group. All procedures were performed on an outpatient basis either under general anesthesia (89%) or paracervical block (11%). The cervix was gradually dilated with Pratt dilators without uterine sounding, and the products of conception were evacuated by plastic suction cannula. This was followed by sharp curettage to ascertain that the uterine cavity was empty. In

cases of continuous bleeding, oxytocin was used in lieu of repeat curettage.

An additional 706 first-trimester abortions were performed with the same method at the time of laparoscopic sterilization. The average age of the patients in this group was 35 years and parity was 2.3. General anesthesia was used in 687 (97.3%) cases and local anesthesia was used in 19 (2.7%) cases. The largest Pratt dilator used for dilatation was reinserted just beyond the internal os of the cervix. It was securely attached to the tenaculum with adhesive tape to mobilize the uterus. Tubal sterilizations were carried out through a single incision by means of bipolar cautery or Falope rings with the aid of video laparoscopy. The procedures were performed by four experienced surgeons.

In the abortion group, uterine perforations were diagnosed by physician suspicion after an instrument was passed beyond the expected distance. This perforation rate was compared with those described in the literature.

In the abortion-sterilization group, the surgeons were asked to report perforations before laparoscopy. The reported rate of uterine perforations could then be compared with those recognized only during laparoscopy.

The p values < 0.05 were considered significant. Calculation of statistical significance between the abortion and laparoscopy-abortion groups was made by the χ^2 test.

Results

Eight uterine perforations were reported during 6408 first-trimester abortions, resulting in a perforation rate of 1.3/1000 procedures. The average age of these patients was 22 years and parity was 0.8. Six of the eight perforations were sustained under general anesthesia.

When the abortions were performed at the time of laparoscopic sterilizations, two perforations were reported before direct visualization (2.8/1000 procedures). Twelve additional perforations were recognized only through the laparoscope. Thus the true incidence of uterine perforations in the laparoscopic group was 14 (two + 12) per 706 cases, or 19.8/1000 procedures. This is sevenfold higher ($p < 0.001$) than the perforation rate recognized with traditional methods. The average age of these 14 patients was 36 years and parity was 2.2. All received general anesthesia. The location of perforations and uterine positions are shown in Table I. Most perforations occurred in the fundus.

Of 22 uterine perforations, three were recognized before and two were discovered during the suction procedure. In five patients the perforation became evident at the time of curettage. Twelve perforations went undetected until laparoscopic sterilization, and the perforating instrument could not be identified.

Table I. Uterine position and location of perforations in the abortion-laparoscopy group

	Uterine position	
Site of perforations	*Anteverted, No.*	*Retroverted, No.*
Fundus or cornua	5	4
Anterior wall	1	3
Posterior wall	1	—
Cervix	—	—

In the 10 patients in whom perforations were recognized without laparoscopy, abortions were completed under sonographic control. In the 12 patients in whom unsuspected uterine perforations were diagnosed at the time of laparoscopic sterilization, no further treatment was required. All 22 patients were discharged on antibiotics an average of 4 hours after the procedure and returned to their normal activities in 48 hours. With the exception of one woman, all returned for postoperative checkup within 2 weeks, which revealed a benign postoperative course and normal pelvic findings.

Comment

The rates of recognized perforations in our abortion group and abortion-sterilization group were 1.3 and 2.8/1000 procedures, respectively, which are similar to those reported in the literature. Twelve additional perforations (15.6/1000 cases) were discovered only during laparoscopic sterilizations, resulting in a true uterine perforation rate of 19.8/1000 procedures in this study group. The secure placement of the Pratt dilator during uterine manipulation prevented accidental perforations. Therefore most traumatic uterine perforations during first-trimester abortions are unreported or even unsuspected. Similar conclusions were reached by White et al.[3] during diagnostic curettage in patients who had subsequent laparoscopy.

On the basis of these data, it is clear that most uterine perforations inadvertently escape medical attention and seldom result in serious complications. We would not deny that serious injuries can be sustained at a time of uterine perforations, but we disagree with Lauersen and Birnbaum[6] and Mittal and Misra's[3] suggestion that all patients with uterine perforations should immediately have laparoscopy or even laparotomy.

If the perforation occurs while the gestational tissue is still present in the uterine cavity, the abortion should be completed under sonographic guidance, avoiding more invasive surgical procedures. If intraoperative ultrasound studies are unavailable or the surgeon is in-

experienced with suction curettage, laparoscopic control is indicated to complete the abortion. Of course, these patients need careful surveillance after surgery.

Our data also confirmed the previously known fact that general anesthesia, advanced age, and parity have been associated with increased incidence of uterine perforations during abortion. However, surgical experience and proper technique can reduce the risk of the perforation, even in these high-risk cases.[7] We recommend a preoperative linear or vaginal ultrasound scanning and careful bimanual pelvic examination under suitable anesthesia. We suggest the use of Pratt dilators without uterine sounding. The suction cannula should only be passed through the internal os of the cervix, and the conceptus should be sucked from this position. The curettage should always be gentle and only to confirm the intended result. An optimally evacuated uterus after abortion seldom bleeds, and the use of uterotonics is recommended rather than repeat over-zealous curettage. Reinsertion of the Pratt dilator for uterine mobilization before laparoscopy should not increase the risk of perforation if it is securely attached to the tenaculum and not passed significantly beyond the internal os of the cervix.

In conclusion, we feel that most uterine perforations during first-trimester abortions go unrecognized and untreated. Therefore we suggest restraint and observation in managing recognized perforations, unless intra-abdominal contents have been brought through the cervix. Careful postoperative monitoring in the recovery room and instructions after discharge will help identify patients requiring more invasive treatment. Our experiences suggest that premature exploratory laparotomies after uterine perforations are unnecessary. We recognize that in the current medicolegal climate, it is a hard decision to make, but a well-balanced judgment in this critical time period on the part of the physician will benefit the overwhelming majority of young women seeking first-trimester abortions.

DEPARTMENT OF OBSTETRICS AND GYNECOLOGY
UNIVERSITY OF WISCONSIN MEDICAL SCHOOL, MILWAUKEE CLINICAL CAMPUS AT SINAI SAMARITAN MEDICAL CENTER

Excellent opportunities for **MATERNAL FETAL MEDICINE** and **GENERAL OBSTETRICS AND GYNECOLOGY** with an interest in **AMBULATORY CARE, UROGYNECOLOGY,** or **STATEWIDE FAMILY PLANNING.** Sinai Samaritan Medical Center is the largest obstetrical unit (4,800 deliveries) in Wisconsin and is a tertiary care referral center in downtown Milwaukee. The University of Wisconsin Medical School, Milwaukee Clinical Campus, supports an active ob/gyn department with consultative ultrasound, genetic, infectious disease and reproductive/endocrine services.

Qualifications include board eligibility or certification in Obstetrics and Gynecology and/or subspecialty. Commitment to teaching residents, medical students, consultative services and clinical research.

Salary open and dependent on qualifications and experience. For more information, interested candidates should contact:

Obstetrics and Gynecology
Maternal/Fetal Medicine Specialist

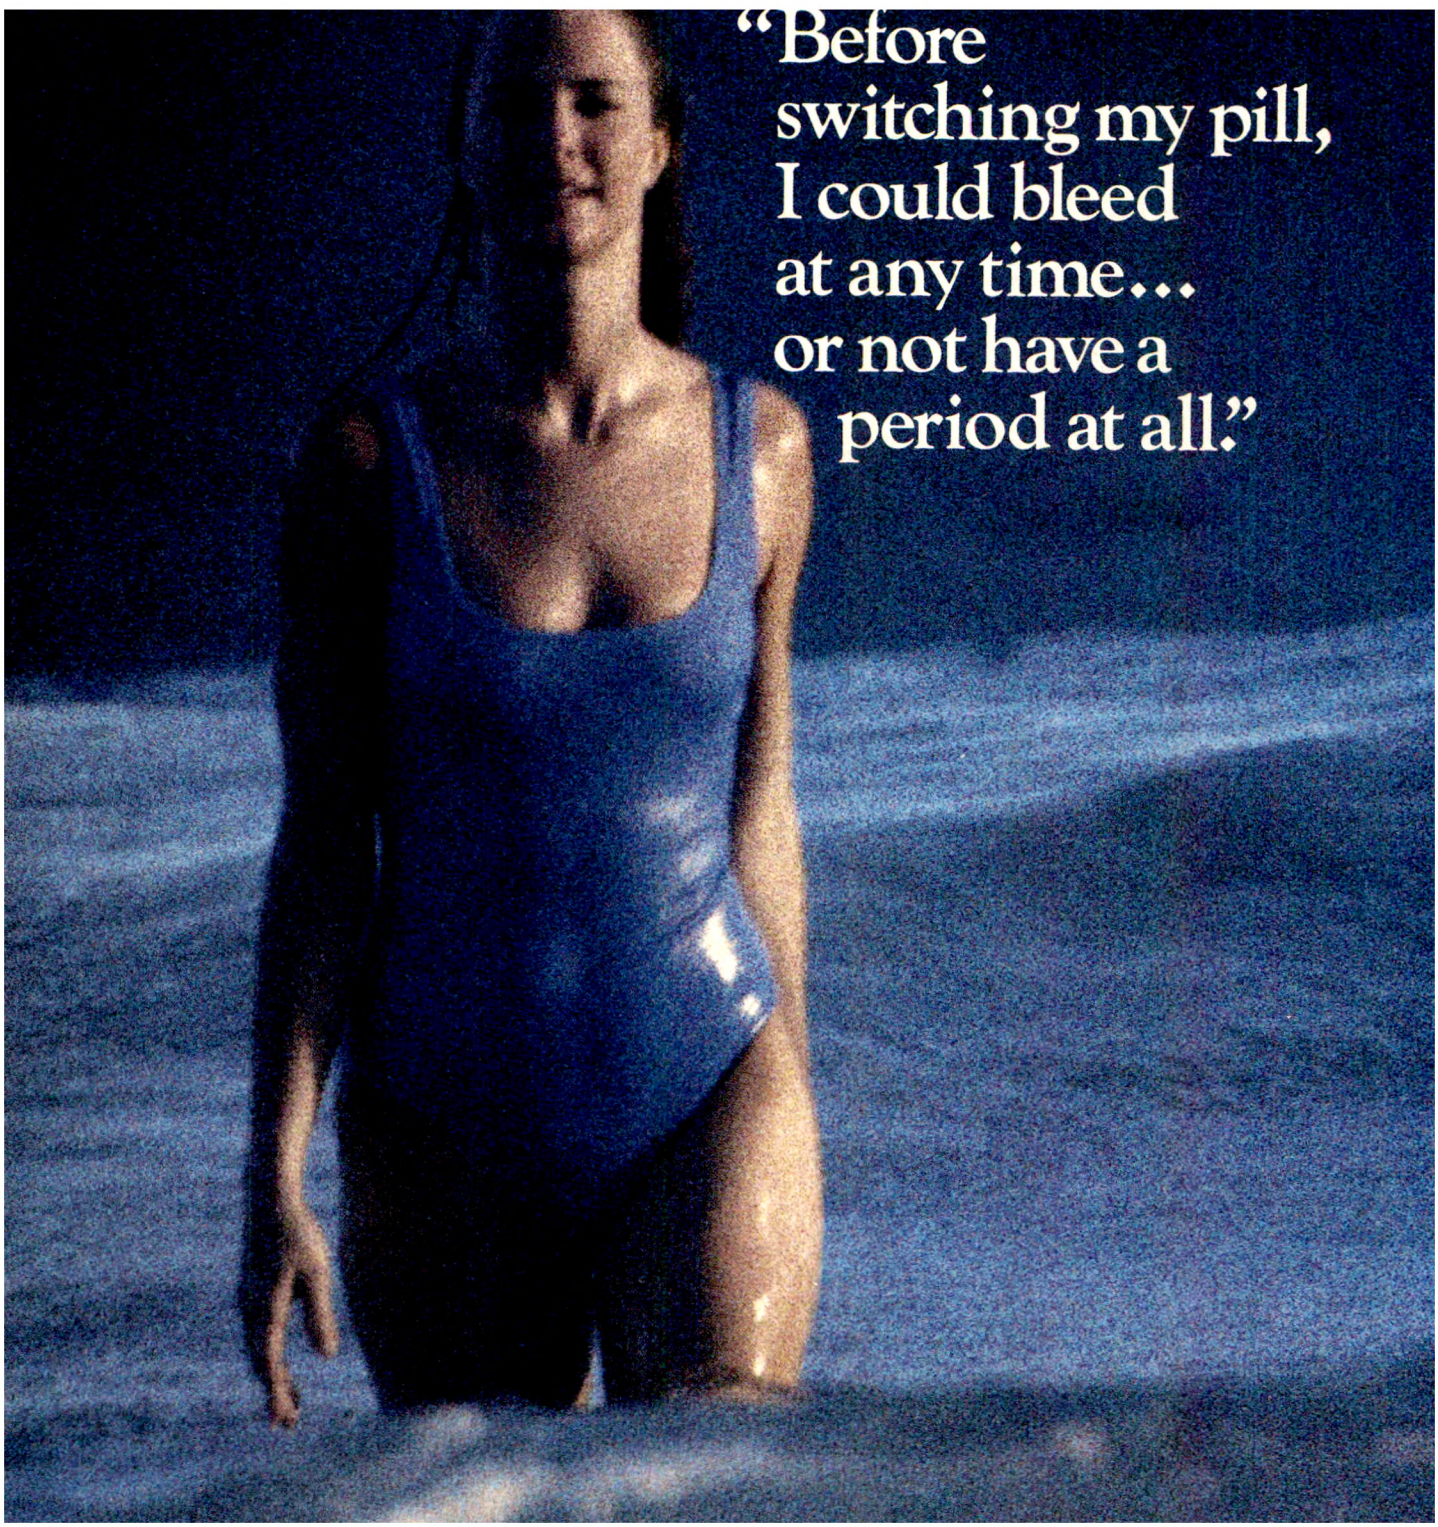
The Western Pennsylvania Hospital is seeking a second BC/BE specialist in Maternal/Fetal Medicine to join a rapidly growing division of Maternal/Fetal Medicine in a 550 bed tertiary care center. This is a unique opportunity in that major teaching, clinical and research opportunities are available in this university affiliated center. A fully accredited independent Ob/Gyn Residency training program is in place. This is a level III tertiary care center with a 30 bed neonatal intensive care unit. The Maternal/Fetal Medicine service accepts high risk maternal transports from throughout the tri-state area. A full range of genetic services are also performed at the institution, including chorionic villi sampling, amniocentesis, and genetic counseling. A research building is currently being built, and opportunities are available for both basic and clinical research. This position offers a state of the art practice opportunity, an attractive compensation package, and the chance for one to be creative. Send your CV to:

Mark Caine, M.D.
Director, Maternal/Fetal Medicine
Department of Obstetrics and Gynecology
West Penn Hospital
4800 Friendship Avenue
Pittsburgh, PA 15224

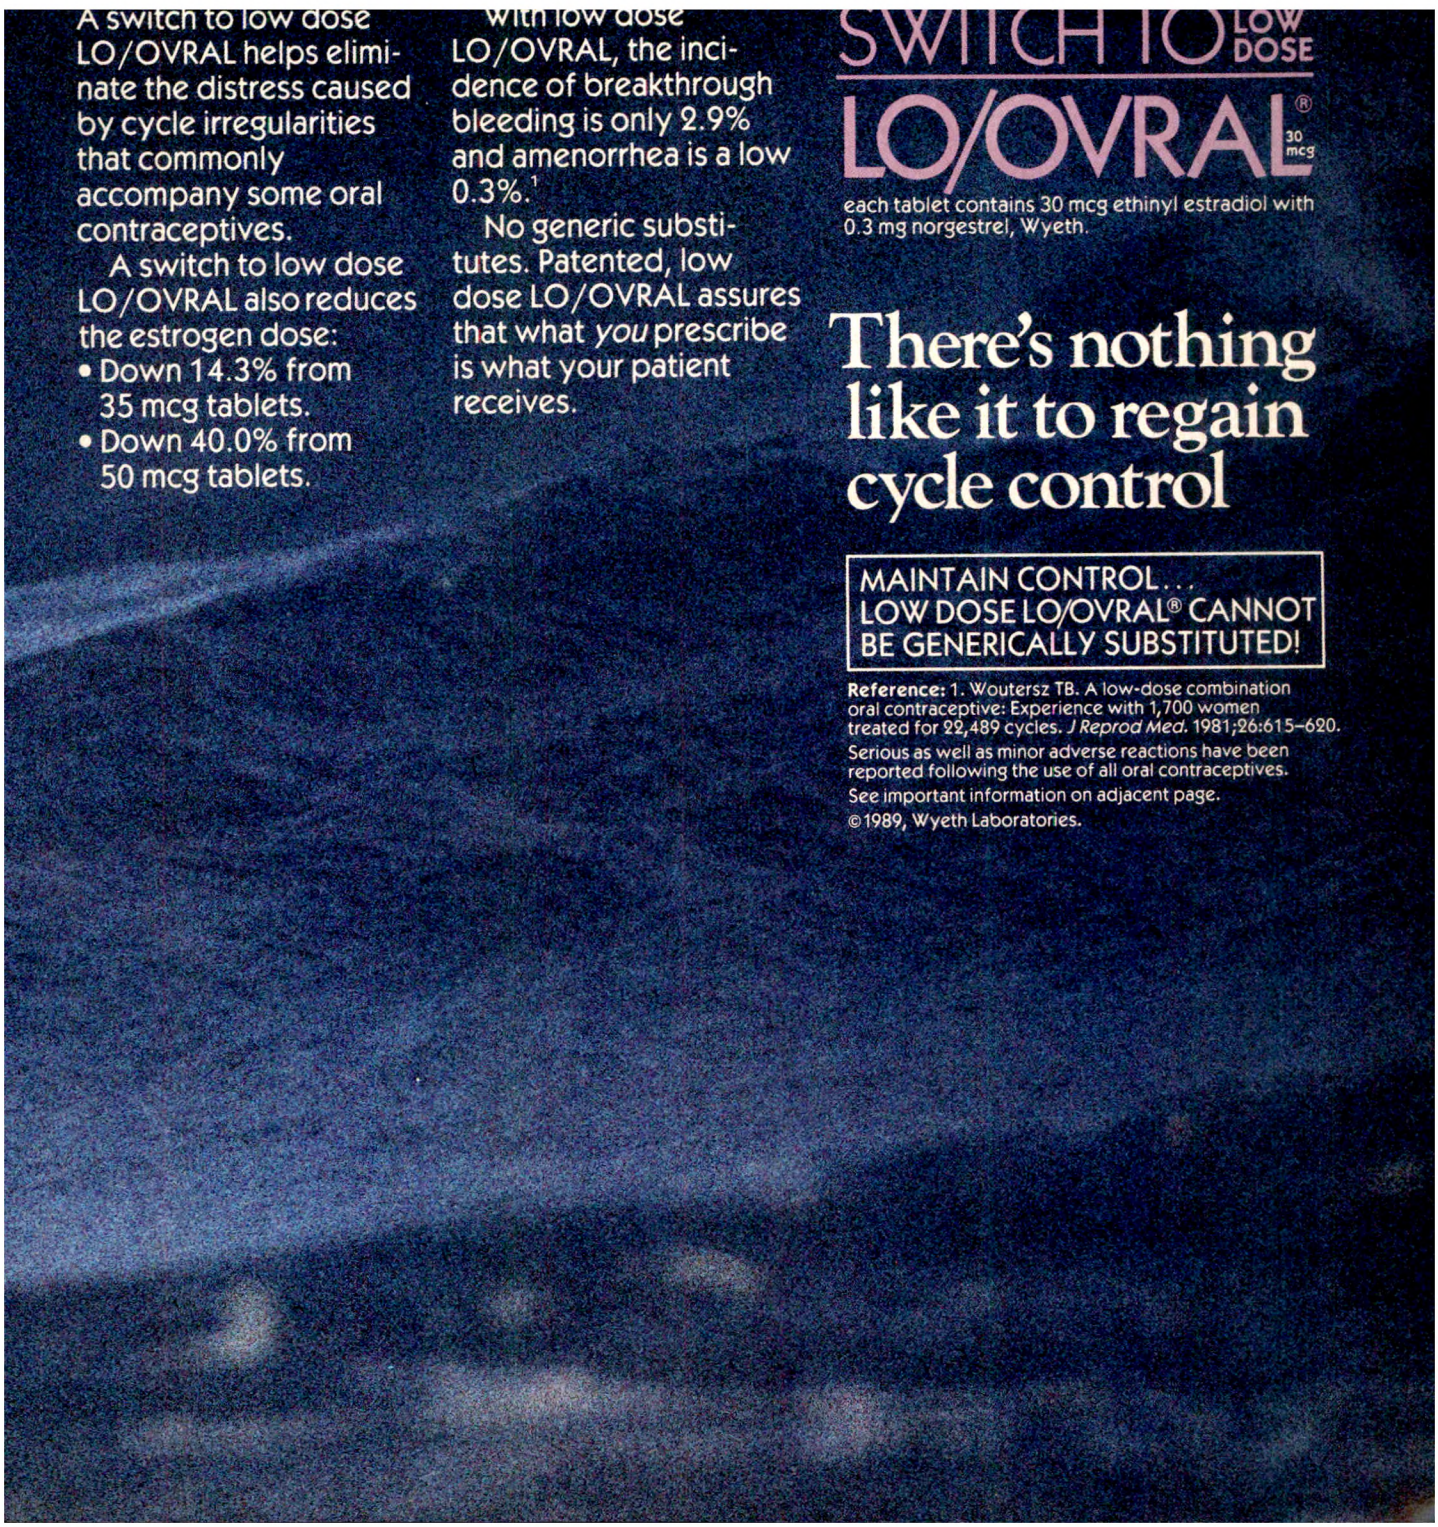
Maternal-Fetal Medicine

The Department of Obstetrics and Gynecology at the University of Tennessee Medical Center at Knoxville, Tennessee is currently accepting applications for an additional Maternal-Fetal Medicine Specialist.

This position requires Board certification or eligibility in Maternal-Fetal Medicine. Responsibilities include resident and medical student education, participation in Regionalization Program and clinical or basic research. Specialized areas of interest such as critical care, ultrasonography and Doppler studies, and prenatal diagnosis are encouraged. A private practice opportunity is available.



Academic rank is commensurate with qualifications and experience.



Interested persons should send curriculum vitae to:

Michael R. Caudle, M.D.
Associate Professor and Gynecology
Department of Obstetrics and Gynecology

"Before
switching my pill,
I could bleed
at any time...
or not have a
period at all."

A switch to low dose LO/OVRAL helps eliminate the distress caused by cycle irregularities that commonly accompany some oral contraceptives.
A switch to low dose LO/OVRAL also reduces the estrogen dose:
• Down 14.3% from 35 mcg tablets.
• Down 40.0% from 50 mcg tablets.
With low dose LO/OVRAL, the incidence of breakthrough bleeding is only 2.9% and amenorrhea is a low 0.3%.[1]
No generic substitutes. Patented, low dose LO/OVRAL assures that what *you* prescribe is what your patient receives.
SWITCH TO LOW DOSE
LO/OVRAL® 30 mcg
each tablet contains 30 mcg ethinyl estradiol with 0.3 mg norgestrel, Wyeth.
There's nothing like it to regain cycle control
MAINTAIN CONTROL... LOW DOSE LO/OVRAL® CANNOT BE GENERICALLY SUBSTITUTED!
Reference: 1. Woutersz TB. A low-dose combination oral contraceptive: Experience with 1,700 women treated for 22,489 cycles. *J Reprod Med.* 1981;26:615–620.
Serious as well as minor adverse reactions have been reported following the use of all oral contraceptives.
See important information on adjacent page.
©1989, Wyeth Laboratories.

IN BRIEF:

Indications and Usage—LO/OVRAL® is indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OC's) as a method of contraception.

Contraindications—OC's should not be used in women with any of the following conditions:

1. Thrombophlebitis or thromboembolic disorders.
2. A past history of deep-vein thrombophlebitis or thromboembolic disorders.
3. Cerebral-vascular or coronary-artery disease.
4. Known or suspected carcinoma of the breast.
5. Known or suspected estrogen-dependent neoplasia.
6. Undiagnosed abnormal genital bleeding.
7. Known or suspected pregnancy (see Warning No. 5).
8. Benign or malignant liver tumor which developed during use of OC's or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems*—An increased risk of thromboembolic and thrombotic disease associated with use of OC's is well established. Three principal studies in Great Britain and 3 in the U.S. have demonstrated increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OC's are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS—In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION (MI)—An increased risk of MI associated with use of OC's has been reported, confirming a previously suspected association. These studies, conducted in the UK, found, as expected, that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of pre-eclamptic toxemia) the higher the risk of developing MI, regardless of whether the patient was an OC user or not. OC's, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to MI) are about twice as likely to have a fatal MI as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal MI compared to users who do not smoke, but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, amount of smoking is also an important factor. In determining importance of these relative risks, however, baseline rates for various age groups must be given serious consideration. Importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; quite likely the same synergistic action exists, but perhaps to a lesser extent.

RISK OF DOSE—In an analysis of data derived from several national adverse-reaction reporting systems, British investigators concluded that risk of thromboembolism, including coronary thrombosis, is directly related to dose of estrogen in OC's. Preparations containing 100 mcg or more of estrogen were associated with higher risk of thromboembolism than those containing 50-80 mcg. Their analysis did suggest, however, that quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the U.S.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES—A large prospective study carried out in the UK estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OC's according to age, smoking habits, and duration of use. Overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), risk being concentrated in older women, in those with long duration of use, and in cigarette smokers. It was not possible, however, to examine interrelationships of age, smoking, and duration of use, nor to compare effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess magnitude of relative risk for this younger group. Available data from a variety of sources have been analyzed to estimate risk of death associated with various methods of contraception. Estimates of risk of death for each method include combined risk of contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OC's) plus risk attributable to pregnancy or abortion in event of method failure. This latter risk varies with effectiveness of method. The study concluded that mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OC's in women over 40 who smoke. Lowest mortality is associated with condom or diaphragm backed up by early abortion. Risk of thromboembolic and thrombotic disease associated with OC's increases with age after about 30 and, for MI, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of pre-eclamptic toxemia, and especially cigarette smoking. Physician and patient should be alert to earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A 4- to 6-fold increased risk of postsurgery thromboembolic complications has been reported in OC users.

If feasible, OC's should be discontinued at least 4 weeks before surgery of a type associated with increased risk of thromboembolism or prolonged immobilization.

PERSISTENCE OF RISK OF VASCULAR DISORDERS—Findings from one study in Britain involving cerebrovascular disease and another in the U.S. concerning MI suggest an increased risk of these conditions in users of OC's persists after discontinuation of the OC's. In the British study, risk of cerebrovascular disease remained elevated in former OC users for at least 6 years after discontinuation. In the U.S. study, increased risk of MI persisted for at least 9 years in women 40- to 49-years-old who had used OC's for 5 or more years. Findings in both studies require confirmation since they are inconsistent with other published information.

2. *Ocular Lesions*—There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with use of OC's. Discontinue OC's if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

3. *Carcinoma*—Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases frequency of carcinoma of the breast, cervix, vagina, and liver. Certain synthetic progestogens, none currently contained in OC's, have been noted to increase incidence of mammary nodules, benign and malignant, in dogs. In humans, 3 case-control studies have reported an increased risk of endometrial carcinoma associated with prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OC's. Of cases found in women without predisposing risk factors (e.g., irregular bleeding at the time OC's were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These are no longer marketed. No evidence has been reported suggesting increased risk of endometrial cancer in users of conventional combination or progestogen-only OC's. Several studies have found no increase in breast cancer in women taking OC's or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women on OC's, found an excess risk in subgroups of OC users with documented benign breast disease. Reduced occurrence of benign breast tumors in users of OC's has been well documented. In summary, there is at present no confirmed evidence from human studies of increased risk of cancer associated with OC's. Close clinical surveillance of all women on OC's is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or with breast nodules, fibrocystic disease, or abnormal mammograms should be monitored with particular care if they elect to use OC's.

4. *Hepatic Tumors*—Benign hepatic adenomas have been found to be associated with use of OC's. One study showed that OC's with high hormonal potency were associated with higher risk than lower potency OC's. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users. Two studies relate risk with duration of use of OC's, the risk being much greater after 4 or more years' use. While hepatic adenoma is rare, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women on OC's. Relationship of these drugs to this type of malignancy is not known.

5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring, and Malignancy in Female Offspring*—Use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have increased risk of developing in later life a form of vaginal or cervical cancer ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence now that OC's further enhance risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OC's. Furthermore, 30 to 90% of such exposed women have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with use of other estrogens, it cannot be presumed they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with use of sex hormones, including OC's, in pregnancy. One case control study estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OC's, hormonal withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some exposures involved only a few days. Data suggest that risk of limb-reduction defects in exposed fetuses is somewhat less than 1 in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OC's. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OC's is unknown. It is recommended that, for any patient who has missed 2 consecutive periods, pregnancy should be ruled out before continuing OC's. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at time of first missed period, and further use of OC's should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and advisability of continuation of the pregnancy should be discussed. It is also recommended that women who discontinue OC's with intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this. The administration of progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease*—Studies report increased risk of surgically confirmed gallbladder disease in users of OC's and estrogens. In one study, increased risk appeared after 2 years' use and doubled after 4 or 5 years' use. In one of the other studies, increased risk was apparent between 6 and 12 months' use.

7. *Carbohydrate and Lipid Metabolic Effects*—Decrease in glucose tolerance has been observed in a significant percentage of patients on OC's. For this reason, prediabetic and diabetic patients should be carefully observed while on OC's. Increase in triglycerides and total phospholipids has been observed in patients on OC's; clinical significance of this finding remains to be defined.

8. *Elevated Blood Pressure*—Increase in blood pressure has been reported in patients on OC's. In some women, hypertension may occur within a few months of beginning OC's. In the 1st year of use, prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. Prevalence in users increases, however, with longer exposure, and in the 5th year of use is 2½ to 3 times the reported prevalence in the 1st year. Age is also strongly correlated with development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure on OC's. Hypertension that develops as a result of taking OC's usually returns to normal after discontinuing the drug.

9. *Headache*—Onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of OC's and evaluation of the cause.

10. *Bleeding Irregularities*—Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing OC's. In breakthrough bleeding, as in all cases of irregular vaginal bleeding, nonfunctional causes should be borne in mind.

In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or change to another OC may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary, since this may increase risk of thromboembolic disease. Women with past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuing OC's. Women with these pre-existing problems should be advised of this possibility and encouraged to use other methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy*—Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast-feeding*—OC's given in the postpartum period may interfere with lactation and decrease quantity and quality of breast milk. Furthermore, a small fraction of the hormones in OC's has been identified in the milk of mothers on OC's; effects, if any, on the breast-fed child have not been determined. If feasible, defer OC's until infant has been weaned.

Precautions—GENERAL—1. A complete medical and family history should be taken prior to initiation of OC's. Pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Pap smear and relevant laboratory tests.

As a general rule OC's should not be prescribed for longer than 1 year without another physical examination.

2. Under influence of estrogen-progestogen preparations, pre-existing uterine leiomyomata may increase in size.

3. Patients with history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while on OC's should stop OC's and use an alternate method to try to determine whether the symptom is drug-related.

4. OC's may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency.

5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence while on OC's. If jaundice develops, OC's should be discontinued.

6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution.

7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. Clinical significance is undetermined.

8. Serum folate levels may be depressed by OC's. Since the pregnant woman is predisposed to development of folate deficiency and incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OC's, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency.

9. The pathologist should be advised of OC therapy when revelant specimens are submitted.

10. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containing OC's: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

Information for the Patient—See Patient Package Labeling.

Drug Interactions—Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.

Carcinogenesis—See Warnings on carcinogenic potential of OC's.

Pregnancy—Category X. See Contraindications, Warnings.

Nursing Mothers—See Warnings.

Adverse Reactions—An increased risk of these serious adverse reactions has been associated with use of OC's (see Warnings): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, benign hepatomas, congenital anomalies.

There is evidence of an association between the following conditions and use of OC's although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients on OC's and are believed to be drug-related: nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally. Gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea, amenorrhea during and after treatment, temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement, and secretion; change in weight (increase or decrease); change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening), intolerance to contact lenses.

The following adverse reactions have been reported in users of OC's, and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, hemolytic uremic syndrome.

Acute Overdose—Serious ill effects have not been reported following acute ingestion of large doses of OC's by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

WYETH AYERST™

Histologic and immunologic study of uterine biopsy tissue of women with incipient abortion

Magdy Michel, MB, MRCOG,[a] Jenny Underwood, BSc, MA,[b] David A. Clark, MD, PhD, FRCPC,[c] James F. Mowbray, MD, FRCP,[b] and Richard W. Beard, MD, FRCOG[a]

London, England, and Hamilton, Ontario, Canada

Biopsy specimens taken from the region of the placental bed were examined for the presence of phloxinophilic granulated mononuclear cells in women with a history of recurrent miscarriage and who would eventually miscarry a current pregnancy. They were compared with biopsy specimens from women with intact pregnancies presenting for elective termination of pregnancy and those with "missed abortion." Cells with large cytoplasmic granules (≥1 μm) were abundant in the group of ongoing pregnancies whereas cells with smaller granules (<1 μm) that were similar to large granular lymphocytes were more abundant relative to cells with large granules in the biopsy specimens from failing pregnancies. Immunosuppressive activity was tested in the supernatants of cultured biopsy samples of each group and found to be significantly lower in the incipient miscarriage group. These findings could represent alterations associated with the process of miscarriage, such as inflammation, or there may be deficient suppressor cell activity at the fetomaternal interface as the reason for "rejection" of the early embryo. (Am J Obstet Gynecol 1989;161:409-14.)

Key words: Aborting women, uterine biopsies in pregnancy, immunologic suppression, fetomaternal relations

The success or failure of the mammalian fetus in an immunologically hostile host has been shown to be correlated to the properties of the tissue at the maternal-fetal interface. Certain types of pregnancies in animals tend to have a high failure rate.[1] Intrauterine destruction of the embryo may be associated with an infiltration by cytotoxic maternal mononuclear cells at the deciduatrophoblastic interface reminiscent of the histologic picture of graft rejection. Both specific cytotoxic T cells and nonspecific natural killer–type cells may be involved. It is proposed that normal human pregnancy involves recognition of the foreign antigen on the conceptus and the development of a subsequent immunologic response. This response is protective to the growing fetus and inhibits maternal cytotoxic cell infiltration by boosting local active suppressor cell activity.[1] Disturbance of this sequence of protective events may lead to an initial miscarriage and recurrence in subsequent pregnancies.

Experimental studies of pregnancy in mice suggest the presence of nonspecific suppressor cells in mechanically disaggregated decidua. These are predominantly small granulated lymphocytic cells that lack T-cell surface markers and elaborate soluble factor(s) that inhibit the response to T-cell growth factor (interleukin-2).[1] Similar interleukin-2 blocking factor(s) has been obtained from human decidua.[2, 3]

In pregnant women distinct differences in the cellular composition of the decidua were noted when healthy and failing pregnancies were compared in 10 samples of placental bed biopsies of four normal women and six women who had begun to miscarry. A paucity of small lymphocytic cells with large granules (stained by phloxine-tartrazine) was evident in the decidua of a failing pregnancy, whereas cells with large granular lymphocytes were prominent in the decidua of miscarrying women.[4] However, this study provided only qualitative rather than quantitative data, and no information was obtained concerning altered immunosuppressor activity in these specimens.

In the study reported here, we quantitatively measured changes in granulated maternal mononuclear cell populations in uterine samples from the area of the placental bed in women who would eventually miscarry and measured the level of suppressor activity in biopsy culture supernatants from this group of patients.

Patients and methods

The study included 59 pregnant women. Group A was a control group consisting of 27 women who un-

derwent legal abortion. Group B consisted of 26 women who had a history of recurrent miscarriage (i.e., three or more unexplained miscarriages with the same partner and not more than one live birth). Group C consisted of six women with an ultrasonographically diagnosed "missed abortion." The average maternal age was 24.9, 33.4, and 29.7 years, respectively, in the three groups.

Group A patients were scanned in the operating room before legal abortion and the gestational age was determined (crown-rump length or biparietal diameter). The presence of fetal heart activity was confirmed and localization of the placenta established.

Group B patients were all investigated at the Recurrent Miscarriage Clinic at the Samaritan Hospital for Women, London, and those found to be lacking antipaternal cytotoxic antibodies were given paternal lymphocyte immunization either before or during pregnancy.[5] Four patients were not immunized in this group, two because antipaternal cytotoxic antibodies were detectable in the sera and the other two because of "anembryonic" pregnancies at the time they were seen for immunization. All patients were followed up by weekly ultrasonographic examination as soon as the test result for the β-subunit of human chorionic gonadotropin was positive. "Anembryonic" pregnancy was diagnosed in all patients in this group and the placental site was determined by ultrasonography. Group C patients had threatened miscarriage (i.e., vaginal bleeding) and were assessed by ultrasonography. Absence of a fetal pole and fetal heart on two separate occasions was considered diagnostic of "anembryonic pregnancy."

Consent was sought from all patients for evacuation

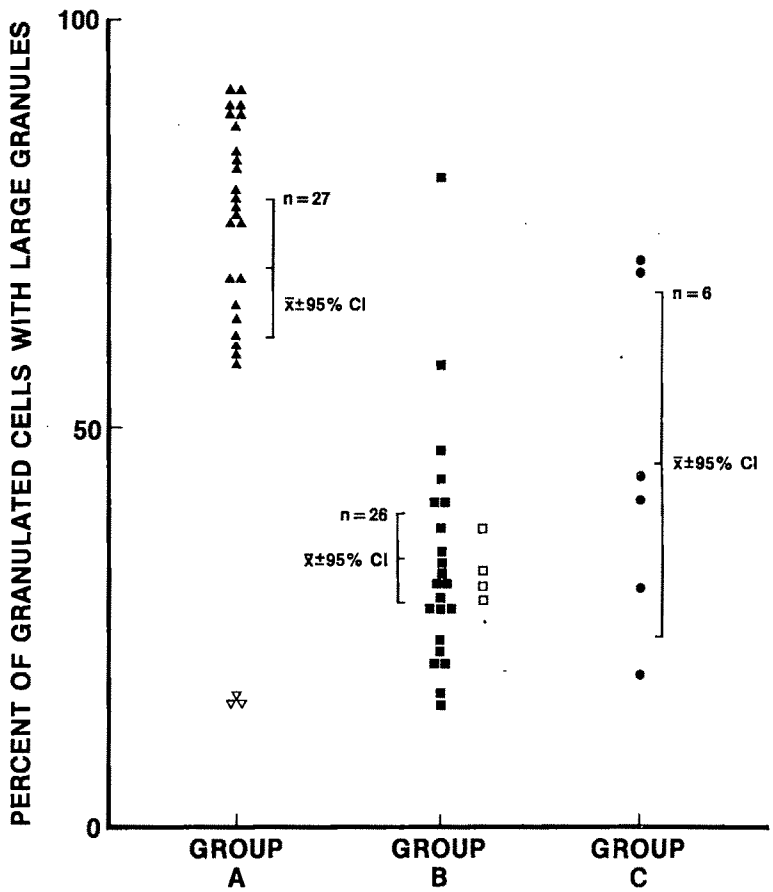

Fig. 2. Percent of granulated mononuclear cells with at least one granule >1 μm. *Group A*, Controls (▲,▽). Geometric mean value ± 1 SEM = 69.4% ± 4.19% (n = 27). Three low values (▽) were from areas with significant increase in numbers of polymorphonuclear leukocytes suggestive of early spontaneous abortion. Excluding these three gives a geometric mean ± 1 SEM = 76.2% ± 2.23%. *Group B*, Women with recurrent spontaneous miscarriage who had not received immunization (□) or had received paternal lymphocyte immunization (■). Mean ± 1 SEM = 33.8% ± 2.65% (n = 26; $p < 0.05$ compared with group A). The value of 81% represented a patient with a trisomy 22. Excluding this value gave a mean ± 1 SEM = 31.9% ± 1.94%. *Group C*, Sporadic abortions (●). Mean ± 1 SEM = 46.5% ± 8.4% (n = 6; $p < 0.05$ compared with control group A).

of the uterus and uterine biopsy under ultrasonographic guidance from the region of the placental bed. With the patient under general anesthesia, the placental site was determined by ultrasonography, the cervix was dilated with Hegar dilators, and cervical biopsy forceps was introduced through the cervical canal to the placental site under direct ultrasonographic guidance. Biopsy specimens including decidual tissue (decidual basalis and superficial myometrium) were taken from the thickest part of the placenta. There were no reported complications from the procedure.

Material obtained was either fixed in Bouin's solution for histologic study or placed in sterile normal saline solution for preparation of supernatant. Fetoplacental tissue was sent for chromosomal analysis. The fixed samples were paraffin embedded, sectioned at 4 μm and stained with phloxine-tartrazine for demonstration of intracellular granules.[4, 6, 7] The slides were scored by two different observers (M. M. and D. A. C.) without knowledge of the clinical details. Large granulated lymphocytes (all granules <1 μm) and cells with large granules (at least one granule ≥1 μm), as described elsewhere,[6] were counted on each slide. Since the biopsy sample was too small to permit disaggregation of the cells for immunologic studies, each sample was weighed and then incubated at 37° C for 48 hours in 1 ml RPMI 1640 medium with antibiotics (100 μg/ml streptomycin, 100 IU/ml penicillin) and 10% fetal bovine serum (Gibco).[4] The cell-free supernatant was then removed and stored at 4° C. The suppressor activity of the supernatant was tested at a 1:4 dilution for suppression of human lymphocyte proliferation. Briefly, sterile heparinized peripheral blood from one of the authors was centrifuged on Isopaque-ficoll (lymphocyte separation medium, density of 1.077) to isolate the mononuclear cells. Viable cells (2×10^5) were incubated with or without test supernatant in replicate round-bottom culture wells (96-well plates, Linbro) in a total volume of 100

Table I. Changes in cell count per slide in biopsy specimens of study population

Patient group	*Cells with large granules*	*Large granular lymphocytes*
Group A		
Log mean ± 1 SEM*	3.72328 ± 0.18744	2.49321 ± 0.17735
Geometric mean†	41.4	12.1
Group B		
Log mean ± 1 SEM*	2.96527 ± 0.21747‡	3.66099 ± 0.16758‡
Geometric mean†	19.4	38.9
Group C

group A, Termination of pregnancy; *group B*, recurrent spontaneous miscarriage (excluding patient with trisomy 22 in Fig. 1); *group C*, missed abortion.

*Data were converted to natural logarithms for calculation of mean and SEM.

†Mean reexpresed arithmetically as the geometric mean (median).

‡$p < 0.05$ by Student's t test, compared with control group A.

μl (minimum essential medium Eagle with alpha modification, 10% fetal bovine serum [Gibco], and antibiotics) for 48 hours with 10 μg/ml concanavalin A. tritiated thymidine was then added (25 μl, final concentration 1 μCi/ml), and the following morning the labeled cells were harvested on glass fiber filters (Skatron cell harvester). The filters were dried and processed for liquid scintillation counting in a β-counter.

The incorporation in counts per minute (average ± SEM) of four replicate wells was calculated, and percentage suppression determined by the formula:

$$\% \text{ Suppression} = 100\left(1 - \frac{\text{counts/min with test supernatant}}{\text{counts/min with medium}}\right)$$

No correction was made for background proliferation occurring in the absence of concanavalin A. Chromosome analysis was not performed on fetoplacental tissue obtained from group A, but 32 samples were cultured from the other two groups. Thirteen samples failed to grow, and two (10.5%) were abnormal (trisomy 47,XX + 22 and 47,XY + 20), both from group B. Chromosome analysis of both parents was normal.

The significance of differences was determined by Student's t test. Log transformation was used where the data followed a log normal distribution.

Results

Cells with large granules were abundant in the decidua of successful pregnancy (Fig. 1, *a*). In contrast, large granulated lymphocytes were frequently seen infiltrating the decidua of women in groups B and C (Fig. 1, *b*). The percentage of granulated cells with large granules for each patient is shown in Fig. 2. It can be seen that the percentage of cells that had large granules was significantly lower in group B than in control group A. The cell population of one of the trisomies, trisomy 22, was clearly in the normal range in contrast to those of the other patients. Group C also showed a reduction in cells with large granules but the number of patients was small.

To determine whether the percentage of cells with large granules had changed in aborting women as the result of a decrease in the number of cells with large granules or rather because of dilution from an increase in the number of large granular lymphocytes, we counted the number of each cell type per slide. There was considerable difference between patients in the total number of granulated cells per slide. In part, this was due to variation in size of the biopsy specimen, but an even greater variation was noted among patients in frequency of granulated cells per microscopic field, most likely caused by sampling differences. In spite of this variability, when the geometric mean of number of cells with large granules per slide and the number of large granular lymphocytes (paired with cells with large granules) per slide were compared for each group of patients, some interesting information was obtained relevant to explaining the decreased percentage of cells with large granules. Where the relative frequency of cells with large granules dropped (in group B), it can be seen (Table I) that the number of cells with large granules decreased and number of large gramular lymphocytes increased compared with group A (i.e., the control group). Group C also showed a decrease in cells with large granules with a smaller increase in large granular lymphocytes. The latter was due in part to somewhat smaller biopsy specimens taken from these six patients.

Suppressive activity in supernatants from the biopsy specimens is shown in Table II. The geometric mean weight was equivalent in groups A and B. Group C samples, as already described, were lighter. Supernatants from group B (excluding one case of trisomy 22 with the percentage of cells with large granules in the normal range and 100% suppression) were significantly

Table II. Suppressor activity in supernatants of placental bed biopsy tissue (donors 7 to 14 weeks' gestation)

Patient group	*Specimen weight (mg)*	*No. of supernatants*	*Suppression of placental bed biopsy tissue (%)*
Group A		17	
Mean ± SEM*	4.85203 ± 0.10545		4.27667 ± 0.06176
Geometric mean†	128		72.0
Group B		13	
Mean ± SEM*	4.84419 ± 0.14954		3.88362 ± 0.19308‡
Geometric mean†	127		48.6
Group C		5	
Mean ± SEM*	4.41884 ± 0.26950		4.08598 ± 0.17974
Geometric mean†	83		59.5
All with abortion (groups B and C)		18	
Mean ± SEM*	4.71850 ± 0.14255		3.93964 ± 0.14834‡
Geometric mean†	112		51.4

The groups are the same as shown in Table I; the patient with trisomy 22 was omitted from group B.
*Data were converted to natural logarithms for calculation of mean and SEM.
†Mean reexpressed arithmetically as the geometric mean (median).
‡Significantly less than the value in control group A. ($p < 0.05$ by Student's t test).

less suppressive than control (group A) specimens. Group C was less suppressive than control group A, but this difference did not reach statistical significance because of small numbers and lighter samples.

Comment

The data in this paper show a decreased number of cells with large granules and an increase in large granulated lymphocytes in placental bed biopsy specimens from women with incipient miscarriage. There was also a decrease in the suppressor activity in these women in comparison with the control group. Women with sporadic miscarriage showed a similar pattern, but the numbers were small. These data confirm earlier reports that a decrease in cells with large granules occurs in association with miscarriages.[4] Although we confined this study to miscarriages <14 weeks' gestation, we have seen similar changes in granulated cell populations in women with gestational ages up to 20 weeks.

There was a low percentage of cells with large granules in three women presenting for termination of pregnancy. These changes were restricted to areas of the biopsy specimen showing focal necrosis, edema, and polymorphonuclear cell infiltration typical of biopsy specimens from women with incipient miscarriage. Low percentages of cells with large granules in biopsy specimens from women who are experiencing a miscarriage could be due to inflammation, which might cause either a dilution by an increase in the number of large granular lymphocytes or a decrease in the granule size related to partial degranulation of the mononuclear cells.

In the mouse, local suppressor cell activity, granulated small suppressor cells, and natural killer cell activity in decidua have been shown to require an implanted embryo for induction.[1, 8] Natural killer cell activity and immunosuppression also have been shown to be due to different cell populations on the basis of size and presence or absence of the asialoganglioside-G_{m1} activation marker.[1] In human decidua, granulated mononuclear cells found near sites of cytotrophoblastic invasion as described by Bulmer and Johnson[9] are phenotypically similar to T-lineage lymphocytes but lack the classic surface markers of mature T cells. Trophoblast cell products appear to activate suppressor function of mononuclear cells in human endometrial-decidual tissue.[10]

Both suppressor cell activity and natural killer cell activity have been partially associated with granulated cells.[11, 12] It has been known for some time that HNK-1^+ (Leu-7^+) human cells (including classic natural killer cells) may be suppressive in vitro.[12] However, cells bearing the HNK-1 (Leu-7) antigen are infrequent in first-trimester human decidua; the Leu-19^+ (NKH-1^+) cell is present and may have both natural killer cell and suppressive activity.[11] However, Leu-19^+ cells isolated by fluorescence-activated cell sorting do not seem to account for all of the suppressor cell activity.[11] This is not entirely surprising because both cells and functional activity may be lost to varying degrees with fluorescence-activated cell sorting. Further, it has been shown in the murine system that there may be a large-sized suppressor cell population in addition to the granulated small lymphocytic suppressor cells.[1] This may also be true in humans.[10] Indeed it is not yet clear if cells with large granules are actually suppressor cells rather than a correlate of a decidua rich in suppressor factors. On the basis of murine data, we would not have expected classic natural killer cells (large granular lymphocytes) (bearing Leu-7 and OKM1) to correlate with suppressor activity.[2] Classic natural killer cells might infiltrate at the time of abortion; alternatively the properties of the Leu-19^+ Leu-7^- cells might change and

granule size decrease. Recently, Starkey et al.[13] described three populations of granulated lymphocytes in human decidua: (1) Leu-19$^+$ CD16$^-$ (Fc receptor), CD2$^-$ (E-rosette receptor); (2) Leu-19$^+$ CD16$^-$, CD2$^+$; and (3) a population of CD16$^+$ Leu-19$^\pm$ cells similar to natural killer cells in peripheral blood (and biopsy specimens from our aborting patients, Fig. 1, *b*). The CD16$^+$ subset was larger and more granular, which is typical of large granular lymphocytes in peripheral blood. All of these cells lacked the CD5 marker of mature T cells and CD3 T-cell receptor. Whether cells with large granules and large granular lymphocytes, as we have defined them, belong to the same lineage or different lineages, as defined by the above phenotypic markers, will ultimately be answered by isolating these cells and correlating their morphologic features with surface markers and function.

It was interesting to find that one of the two trisomies in the group studied had a percentage of cells with large granules in the normal range and high suppressive activity. A similar phenomenon has been noted in mice with genetic abortion where the fetus died as the result of lethal effects of T/t locus genes.[6] It is tempting to speculate from our data that a decrease in total number of decidual suppressor cells and cells with large granules is associated with miscarriage caused by "rejection." Recent studies in aborting mice suggest that natural killer–like nonspecific effector cells may be involved in rejection and that the suppressive factor in decidual supernatants is closely related to transforming growth factor-β that blocks interleukin-2, interleukin-3, and interferon-γ activation of nonspecific effector cells including lymphokine activated killer cells, natural killer cells, natural cytotoxic cells, and macrophages.[14] Natural killer cells, natural cytotoxic cells, and macrophages produce tumor necrosis factor-α that can cause cytotoxic effects on tumor cells and the local vascular supply.[15] Immunization with paternal cells of women with a history of recurrent miscarriage may prevent miscarriage and boost local suppression. The women we studied, however, were those who had failed treatment. Immunization apparently had failed to increase the local suppressive activity in this subset of women with recurrent miscarriage.

Defective hemochorial placentation as a result of inadequate trophoblast invasion of decidua also has been associated with miscarriages and is not necessarily linked to fetal chromosomal abnormality.[16] It will be important to determine if a decrease in the number of cells with large granules and suppressive activity also correlates with inhibition of trophoblastic invasion by tumor necrosis factor-α or related toxins in aborting women.

Biopsies of uterine decidua from the placental bed could give useful information regarding whether pregnancy failure is caused by failure of the trophoblast or rather is a result of genetic fetal death. The cellular and molecular basis for protection by local suppressor cells and factor is now under further investigation and should lead to further understanding of the mechanism of pregnancy failure and how immunotherapy may rescue a potentially "doomed" embryo.

Randomized trial of diet versus diet plus cardiovascular conditioning on glucose levels in gestational diabetes

Lois Jovanovic-Peterson, MD,[a] Eric P. Durak, MSc,[a,b] and Charles M. Peterson, MD[a]
Santa Barbara, California, and New York, New York

We studied the impact of a training program on glucose tolerance in gestational diabetes mellitus. Women with gestational diabetes mellitus ($N = 19$) were randomized into either group I, a 6-week diet alone group (24 to 30 kcal/kg/24 hours; 20% protein, 40% carbohydrate, 40% fat), or group II, which followed the same diet plus exercise (20 minutes three times a week for 6 weeks). An arm ergometer was used to maintain heart rate in the training range. Glycemic response was monitored by glycosylated hemoglobin, a 50 gm oral glucose challenge with a fasting and 1-hour plasma glucose, and blood glucose self-monitoring, fasting and 1 hour after meals. Week 1 glycemic parameters were the same for both groups. Week 6 data (mean ± SD) were as follows: group I glycosylated hemoglobin, 4.7% + 0.2% versus group II, 4.2% ± 0.2%; $p < 0.001$. The group I glucose challenge fasting value was 87.6 ± 6.2 versus 70.1 ± 6.6 mg/dl, $p < 0.001$ for group II. The group I 1-hour plasma glucose challenge result was 187.5 ± 12.9 mg/dl versus 105.9 ± 18.9 mg/dl for group II, $p < 0.001$. The glycemic levels diverged between the groups at week 4. We conclude that arm ergometer training is feasible in women with gestational diabetes mellitus and results in lower glycosylated hemoglobin, fasting, and 1-hour plasma glucose concentrations than diet alone. Arm ergometer training may provide a useful treatment option for women with gestational diabetes mellitus and may obviate insulin treatment. (Am J Obstet Gynecol 1989;161:415-9.)

Key words: Gestational diabetes, exercise, glucose tolerance, pregnancy, arm ergometry

Gestational diabetes mellitus is the most common medical complication of pregnancy. Current management consists of diet and careful monitoring of fasting and postprandial glucose levels. The goal of therapy is maintenance of euglycemia. When euglycemia is not achieved by diet alone, insulin therapy is recommended.[1] Gestational diabetes mellitus is considered in part to be a disease of glucose clearance, although it has been shown that this disorder is a heterogeneous entity.[2] Initiation of insulin therapy per se is palliative, but does not address the primary defect(s) that may include hyperinsulinemia. Rather, treatment modalities that overcome a peripheral resistance to insulin such as sulfonylurea treatment or exercise might be preferable. Although the sulfonylurea agents are reported to increase insulin sensitivity,[3] these agents are contraindicated for use in gestational diabetes in the United States.[4]

Cardiovascular conditioning exercise facilitates glucose utilization inter alia by increasing insulin binding to and affinity for its receptor.[5] Although exercise during pregnancy has been gaining acceptance,[6] it remains controversial.[7-15] Specifically, maternal exercise on a bicycle ergometer has been associated with fetal bradycardia.[7,11] Therefore we designed a study that used arm ergometry, which has not been associated with either uterine activity or fetal bradycardia,[16] to evaluate the impact of a training program on glucose tolerance in gestational diabetes mellitus.

Material and methods

Subjects and study design. All women gave informed witnessed consent for the studies that were approved by appropriate institutional review. Table I characterizes the study population and infant outcome. Twenty untrained women with gestational diabetes diagnosed according to standard protocol[1] (Table I) were recruited. One woman was dropped from the study because she was found to have placenta previa and therefore could not be entered. Thus 19 women were randomized into two groups by drawing a number (group I or group II). The randomization process revealed that the peak plasma glucose response at 1 hour after a 50 gm glucose load was not significantly different in the two groups at the start of the program, whereas the peak 1-hour plasma glucose in group I on the 100 gm glucose tolerance test was significantly lower than in group II (Table I). The 50 gm glucose test with a fasting and 1-hour plasma glucose level will be referred to in this paper as the glucose challenge test.

Each woman was instructed to perform blood glucose

GTT, glucose tolerance test.
*Group I versus group II.

self-monitoring four times daily (before breakfast and 1 hour after each meal). Each week all subjects were seen by a physician. Insulin was to be initiated if the fasting plasma glucose level rose higher than 105 mg/dl[1] and/or the 1-hour postprandial plasma glucose level was >140 mg/dl.[17] Serial evaluation of the glucose challenge test included a fasting plasma glucose, a 50 gm oral glucose load, and a 1-hour plasma glucose study. Plasma glucose was obtained by venipuncture and analyzed by the glucose oxidase method. The glucose challenge test was performed before and after the 6-week protocol. A fasting C-peptide specimen was drawn with the fasting plasma glucose determinations.

Group I was managed for 6 weeks with a standard diet that consisted of 40% carbohydrate, 20% protein, and 40% fat calculated at 24 to 30 kcal/kg/24 hours present pregnant weight divided into three meals and three snacks.[18] These women did not participate in any structured exercise program. Weekly questionnaires revealed that their only form of exercise was cleaning, shopping, and "running after toddlers." Group II received the same diet and participated in an exercise program of 6 weeks' duration that consisted of 20 minutes of supervised aerobic training on an arm ergometer (UBE-Cybex Fitness, Ronkonkoma, N.Y.). Six women exercised in the afternoon, between 4 PM and 5 PM (3 hours after the last meal) and four of the women exercised in the morning between 10 and 11 AM (3 hours after breakfast). These times were chosen because the blood glucose levels in the diet alone group were stable and comparable at these time points.

The patients were monitored for 20 minutes of cardiovascular work during which they maintained their target heart rate,[11] which was calculated to be equal to (220 − age in years) × 70% unless this heart rate exceeded 140 beats/min; then 140 beats/min was the target heart rate.[6] As each patient adapted to her workload in terms of perceived exertion and heart rate, the workload (or resistance) (kg × meters × min^{-1}) was increased or decreased by 10% to 20%; thus maternal heart rate was maintained in the training range. The exercise session never exceeded 50% maximal oxygen consumption ($\dot{V}O_{2\,max}$) in any case. Fifty percent oxygen consumption was estimated based on our previous work that related maternal heart rate in beats/min to the $\dot{V}O_2$ at steady state utilizing a metabolic cart (Beckman model S/N 614, D/N 11265, Fullerton, Calif.).[11] Blood glucose levels were measured before and after each exercise session. In over 150 sessions of exercise with the arm ergometer with pregnant women, no fetal

bradycardia or uterine activity has been observed. The caloric expenditure associated with this form of exercise is equal to the expenditure on a bicycle ergometer at the same heart rate for the same duration, provided that the test method utilizes the same muscle groups trained by the regimen.[19]

Laboratory evaluation. The plasma glucose level was measured by glucose oxidase (Yellow Springs Instruments, Yellow Springs, Ohio). Glycosylated hemoglobin was analyzed by high-pressure liquid chromatography.[20] The normal range for glycosylated hemoglobin in pregnancy is 3.5% to 4.5%, and the mean glycosylated hemoglobin is 4.0 ± 0.250, based on 100 pregnant women who had normal glucose tolerance tests. C-peptide was analyzed by radioimmunoassay according to the manufacturer's instructions (Novo Biolabs Antiserum M1221, Bagsverd, Denmark).[21] The normal range in pregnancy is 0.5 to 2.0 pmol/ml.

Fetal heart rate and uterine activity were measured continuously for 10 minutes before, during, and after exercise with a fetal monitor (Corometrics model 111 fetal monitor, Wallingford, Conn.). Uterine activity was expressed as a percent of total exercise time (minutes of contraction/total minutes of exercise × 100). A contraction was defined as a tocometer deflection >15 mm Hg above baseline.

Statistical analysis. Statistical analysis used the STATWORKS program on the Macintosh PC. Paired or unpaired *t* tests were used to analyze the data as appropriate. All mean values are expressed as ± 1 SD.

Results

Groups I and II did not differ (Table I) in maternal age (31.1 ± 2.8 vs. 29.5 ± 2.5 years, $p = 0.203$), maternal weight at the start of the program (75.3 ± 8.2 vs. 78.4 ± 9.7 kg, $p = 0.471$), maternal C-peptide level (range 1.87 to 3.0 vs. 1.95 to 3.0 pmol/ml), gestational age at delivery (range 39.4 to 40.0 vs. 39.5 to 40.5 weeks), neonatal birth weight (3465 ± 343 vs. 3634 ± 317 gm, $p = 0.282$), or gender of the infants (5 females

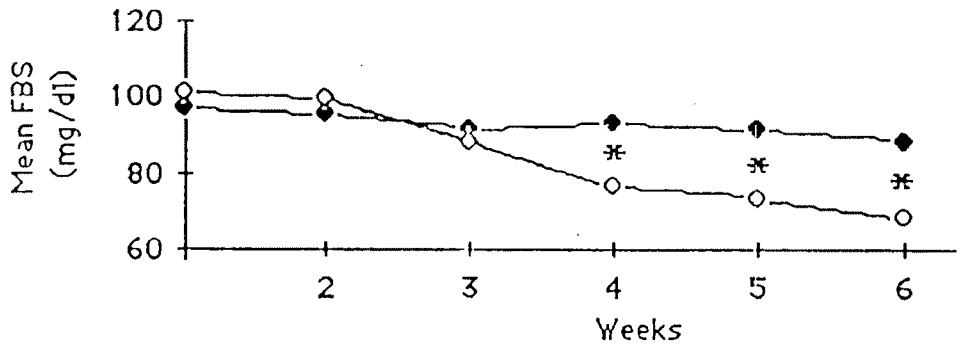

Fig. 1. Weekly mean fasting blood glucose (milligrams per deciliter) of blood glucose self-monitored results from week 1 to week 6 of protocol. *Closed circles* (●) represent mean values for group I (diet alone) and *open circles* (○) represent group II (diet and exercise). *Asterisk* signifies significance of $p < 0.001$.

vs. 5 females). The 1-hour plasma glucose value on the diagnostic glucose tolerance test did differ between the groups: group I, 221.3 ± 35.7 vs. group II, 263.5 ± 27.2 mg/dl ($p = 0.01$).

Despite the difference in the diagnostic glucose tolerance test results, at the beginning of the protocol groups I and II had equivalent 1-hour blood glucose responses (Tables II and III) to a glucose challenge test (group I = 225.8 ± 32.8 mg/dl vs. group II = 230.8 ± 28.5 mg/dl, p = NS). After 6 weeks, the mean 1-hour glucose response in group I on the glucose challenge test was 187.5 ± 12.9 mg/dl compared with the women in group II, who had a mean 1-hour response of 105.9 ± 18.9 mg/dl ($p < 0.001$, group I vs. group II). Group I did improve their 1-hour glucose response to a challenge with the program of diet alone (initial vs. final $p = 0.005$) but the mean 1-hour glucose response on the glucose challenge test was still greater than the current cutoff for the initial screening value for the diagnosis of gestational diabetes of 140 mg/dl[1] (Table II).

The chronic effect of exercise on hepatic glucose output was reflected by the fasting plasma glucose levels on the glucose challenge tests before and after the 6-week protocol. The mean fasting plasma glucose value in group I was 97.8 ± 12.7 mg/dl during the first glucose challenge test and 87.6 ± 6.2 mg/dl on the glucose challenge test after 6 weeks of diet alone ($p = 0.043$). The mean initial fasting plasma glucose value on the glucose challenge test in group II was 100.4 ± 9.3 mg/dl ($p = 0.478$ group I vs. group II). After 18 training sessions, the mean final fasting plasma glucose on the glucose challenge test performed between 15 to 45 hours after the eighteenth session for group II was 70.1 ± 6.6 mg/dl ($p < 0.001$ initial fasting plasma glucose in group II vs. the final). The mean fasting plasma glucose on the final glucose challenge test in group II was also significantly lower than the final value for group I ($p < 0.001$).

The glycosylated hemoglobin level improved in both groups. In group I the mean initial glycosylated hemoglobin value was 4.86% ± 0.39%; after 6 weeks this level fell to 4.67% ± 0.25% ($p = 0.01$). In group II the initial glycosylated hemoglobin value was 4.83% ± 0.33%, which fell to 4.16% ± 0.28% ($p < 0.001$). The glycosylated hemoglobin values for the two groups were not different at the start ($p = 0.75$) but there was a significant difference ($p < 0.001$) after 6 weeks.

To determine the time course of the glucose changes in group I and group II, the daily blood glucose self-monitoring of fasting values for each group were evaluated (Fig. 1). By 4 weeks of the protocol, the mean fasting blood glucose for group II (75.8 ± 5.8 mg/dl) diverged significantly ($p < 0.001$) from that of group I (93.1 ± 6.5 mg/dl). The postprandial glucose levels on self blood glucose monitors in group I were higher than those of group II at the 6-week point (136 ± 10 mg/dl vs. 112 ± 10 mg/dl, $p < 0.01$).

The 10 women who trained (group II) showed a continuing and significant change in glucose response to exercise. On the first day of the training program, the mean glucose decrement during exercise expressed as a percent was 8.4% ± 3.0%. During the eighteenth and final training session, the mean decrement was 29.8% ± 8.0% ($p < 0.001$, initial vs. final percent decrease associated with a training session).

There were no episodes of fetal bradycardia or uterine activity noted during any exercise session. No episodes of hypoglycemia (blood glucose <60 mg/dl) occurred in the study population. None of the 19 women in group I or group II required insulin. Of note, the woman with gestational diabetes who was dropped from the study and who was placed on strict bed rest as a result of placenta previa, did require insulin. All 19 infants born to this study were healthy, term neonates with no signs of morbidity.

Comment

Our study documents that women with gestational diabetes can train with arm ergometry and that such a

program of cardiovascular conditioning exercise results in lower levels of glycemia than a program of diet alone. The effects of exercise on glucose metabolism became apparent after 4 weeks of training and appeared to impact hepatic glucose output (as reflected by fasting glucose levels), glucose clearance (as reflected by glucose values after a 50-gm oral glucose challenge), and mean blood glucose (as reflected by glycosylated hemoglobin values). These combined observations would be consistent with a long-term effect of exercise rather than a short-term effect from individual sessions. The important question of the duration of a training effect on glucose metabolism in women with gestational diabetes was not addressed in this study.

Our observations appear contrary to the results in the literature asserting that the natural progression of glucose intolerance during gestation is deterioration with increasing gestational week[22] and that walking exercise in type I insulin-dependent diabetic pregnant women is associated with no improvement.[23] However, neither of the above studies addressed the issue of gestational diabetes with its unique problems of glucose homeostasis.

The implications of our study for the health care of women with gestational diabetes remain to be determined. Compliance with the protocol was 100% and there was no maternal or infant morbidity associated with the training program in this small series. Our results also imply that a cardiovascular conditioning program might obviate insulin treatment in many women with gestational diabetes. Therefore the economic and health care implications of these observations warrant further testing.

Thrombosis prophylaxis in pregnancy with use of subcutaneous heparin adjusted by monitoring heparin concentration in plasma

Thomas C. Dahlman, MD, Margareta S. E. Hellgren, MD, and Margareta Blombäck, MD
Stockholm, Sweden

Twenty-six pregnant women were given prophylactic heparin treatment because of previous thromboembolic complications. The mean duration of treatment was 25 weeks (range, 6 to 32 weeks). The amount of heparin was adjusted to a plasma concentration of 0.08 to 0.15 IU/ml, measured as anti–factor Xa activity. This effect was compared with that on activated partial thromboplastin time. The average dose was 16,400 IU/24 hours or 225 IU/kg of body weight per 24 hours. When the plasma concentration was within the stipulated range, the dose was 234 IU/kg of body weight/24 hours. No significant prolongation of activated partial thromboplastin time was found in two thirds of the samples. Blood coagulation was either not activated or only slightly activated, as verified by a low level of fibrinopeptide A. Platelet counts and antithrombin III levels were generally not depressed. No thromboembolic complications occurred during the pregnancies or puerperium. Bleeding during delivery was not increased. No fractures of the spine caused by osteoporosis were found on radiologic examination post partum. (Am J Obstet Gynecol 1989;161:420-5.)

Key words: Pregnancy, thrombosis prophylaxis, heparin concentration, activated partial thromboplastin time, antithrombin III, fibrinopeptide A

The incidence of thromboembolic complications in pregnancy is about 1 in 1000.[1-3] About twice the incidence is found in the puerperium.[1,2] A previous history of thromboembolic complications is considered to give a risk of new thromboembolic complications in pregnancy of about 1 in 10.[4,5] Today we treat such women with prophylactic heparin treatment during pregnancy and the puerperium.[2] This has also been the policy of others.[3,6-8] Osteoporosis is a rare but feared complication of long-term heparin treatment.[2,3,5] Whether the incidence of osteoporosis is related to the amount of heparin given or to the duration of treatment is not fully understood. The effect of heparin on blood coagulation has to be measured in some way because the effect of a given dose varies among patients. This effect can be evaluated by measurement of the activated partial thromboplastin time, the heparin concentration as anti–factor Xa activity, and the level of fibrinopeptide A.[9,10] The sensitivity of activated partial thromboplastin time to small doses of heparin used as prophylaxis against thromboembolic complications is low. However, when heparin is measured as anti–factor Xa activity, an anticoagulant effect can be detected at a level as low as 0.02 IU/ml plasma.[11] During prophylactic heparin treatment, a concentration of heparin of approximately 0.1 IU/ml has been considered satisfactory, based on results obtained with subcutaneous low-dose heparin.

In this study the heparin dose has been adjusted by determining the anti–factor Xa activity as measured with chromogenic substrate S-2222. The fibrinopeptide A level was analyzed to detect abnormal activation of the blood coagulation. Antithrombin III levels and platelet counts previously have been reported to decrease during heparin treatment.[2,12,13] Therefore these variables were also monitored. Our purpose was to determine whether the heparin dosage could be kept low with a measurable anticoagulant effect of heparin, adjusted according to the anti–factor Xa activity, without activation of blood coagulation or rethrombosis.

Patients and methods

Twenty-six women with a previous history of thromboembolic complications were given prophylaxis against new thromboembolic complications in connection with pregnancy and the puerperium. The study was approved by the Ethics Committee of Karolinska Hospital. No patient with prophylaxis because of a markedly increased risk of thromboembolic complications (e.g., as a result of artificial heart valves or con-

genital antithrombin III deficiency) was included in the study. The mean age was 28 years (range, 19 to 42). The mean pregestational weight was 65 kg (range, 51 to 108), and the average increase of weight during pregnancy was 11 kg (range, 4 to 21). Eleven patients were nulliparous, 11 were primiparous, and four were secundiparous. Nine of the 26 women were smokers. Nineteen of the patients breast-fed their infants for longer than 6 weeks. One did not breast-feed. As shown in Table I, 11 women had thromboembolic complications during pregnancy, 3 in the puerperium, 7 when taking oral contraceptives, and 2 after operation. In three women no obvious reason for thromboembolic complications was found. The location of thromboembolic complications is also shown in Table I.

Thromboprophylaxis was provided in the form of unfractionated standard sodium heparin prepared from pig intestinal mucosa (Kabi AB). The patients injected themselves subcutaneously in the thigh or the hip every 12 hours during pregnancy. The plasma volume increases and hemostasis is changed during pregnancy in such a way that the need for heparin to achieve the same anticoagulant effect varies during different gestational periods.[14, 15] Furthermore, there is currently no ideal method for measuring antithrombotic effects of heparin, but there are sensitive methods for analyzing the anticoagulant effect. Therefore we chose to measure the anticoagulant effect to give the same treatment early and late during pregnancy, if possible. The dosage of heparin was adjusted to a plasma concentration (determined as the anti–factor Xa activity) corresponding to 0.08 to 0.15 IU/ml measured 3 hours after the morning dose of heparin because subcutaneous heparin reaches its maximum level in pregnant women 2 to 3 hours after injection.[14, 15] Heparin treatment was usually started early in pregnancy (mean, thirteenth week; range sixth to thirty-first week). During labor heparin was given in small doses (initially 5000 IU subcutaneously and then 2500 IU subcutaneously every 8 hours until parturition) in 20 patients. Dextran 40, 500 ml twice with 4-hour interval, was given after administration of a hapten to dextran (Promiten, Pharmacia, Uppsala) to the other six patients.[16] After delivery the amount of heparin was either 10,000 or 15,000 IU/24 hours, depending on the need for heparin before delivery. Heparin treatment was discontinued 6 weeks after delivery, when blood coagulation is generally normalized.[17] Blood loss was measured by volumetric measurements of shed blood and by grossly estimating the blood in gauzes.

On the fifth day post partum, all patients were examined by x-ray of the spine and hip to exclude osteopenia and compression fractures as a result of heparin-induced osteoporosis. Thirty matched normal women were examined at the same time and served as control subjects. The films were later mixed and judged by one experienced radiologist in this field without knowledge of the history of the individuals.

Blood samples were drawn by venipuncture approximately 3 hours after the morning dose of heparin. The sampling and analyses were performed approximately every fourth week until the thirtieth week of pregnancy, every second week until the thirty-sixth week, and thereafter every week until delivery. If the heparin dosage had to be changed, sampling was repeated within a week of the adjustment.

Platelet counts were measured by means of an automatic counter. The blood was centrifuged for the remainder of the analyses. Activated partial thromboplastin time was immediately analyzed according to the manufacturer's directions (Nyegaard, Oslo; reference value <35 seconds). The remaining plasma sample was kept frozen at −70° C until analyzed. The heparin concentration was measured within 3 to 4 days as anti–factor Xa activity with the chromogenic peptide substrate S-2222 (Kabi AB).[11] Fibrinopeptide A (a small peptide that splits from fibrinogen when attacked by thrombin to form fibrin) was measured by radioimmunoassay.[18] The reference value for fibrinopeptide in our laboratory for nonpregnant women is <2 ng/ml, and in early and late pregnancy 1.7 ± 0.8 and 2.5 ± 1.4 ng/ml respectively.[15] Antithrombin III was measured with the chromogenic peptide substrate S-

2238 (Kabi AB).[19] The reference value (mean ± SD) for pregnant women does not differ from that of nonpregnant young women (103% ± 11% of normal; $n = 40$).[15] All analyses were performed in duplicate.

Statistical analysis. The variability in the amount of heparin needed to achieve an adequate anticoagulant effect during different periods of pregnancy was studied by analysis of variance. A p value <0.05 was considered significant.

Results

No clinical thromboembolic complications occurred during pregnancy, parturition, or the puerperium.

No case of vertebral fracture was found on radiologic examination on the fifth day post partum. Four of the 26 heparin-treated patients, but none of 30 controls, were considered osteopenic. These findings are included in a more extensive study, which is under compilation.

There was one intrauterine death at 38 weeks' gestation. No specific explanation was found. The other 26 infants (one pair of twins) were healthy. The birth weights of the infants were appropriate for gestational age. The mean weight was 3190 gm (range, 2280 to 5300 gm). Most infants were delivered in week 38 of pregnancy (range, 36 to 41 weeks). Labor was induced in 17 of 26 pregnancies with a ripe cervix to avoid spontaneous labor before heparin reduction. The mean week of induction was the thirty-ninth week (range, 37 to 41). In one case an elective cesarean section was performed because of placenta previa marginalis. All other women were delivered vaginally. Bleeding during delivery averaged 320 ± 230 ml (mean ± SD). Three patients lost >600 ml of blood. In one patient the blood loss was 1100 ml because of uterine atonia. The patient delivered by cesarean section had a blood loss of 800 ml. The third patient lost 700 ml of blood for unknown reasons. All three had normal activated partial thromboplastin times before delivery.

The average duration of heparin treatment was 25 weeks (range, 6 to 32). The total mean dose given per 24 hours was 16,400 IU (range, 13,000 to 23,000) or 225 IU/kg body weight per 24 hours (range, 190 to 250 IU/kg body weight per 24 hours). The average heparin dosage, the number of patients within the stipulated plasma concentration range during different weeks of pregnancy, the heparin concentration, the mean activated partial thromboplastin time, and the mean fibrinopeptide A level are shown in Table II. When the plasma heparin concentration was within the stipulated range, the mean dose was 234 IU/kg body weight/24 hours (range, 191 to 245 IU/kg body weight per 24 hours; Table II). In early pregnancy the average heparin dose needed to achieve the stipulated anticoagulant effect was 228 IU/kg body weight per 24 hours (Table II). Thereafter, the need for heparin increased to a maximum between weeks 21 and 30. The patients then required on average 245 IU/kg body weight per 24 hours (Table II). During the remaining weeks of pregnancy, the need of heparin decreased, but not significantly. The total changes in need for heparin in

APTT, Activated partial thromboplastin time (reference value, <35 seconds).

relation to gestational age were significant ($p < 0.025$, analysis of variance; Table II). The need for heparin is plotted and demonstrated in Fig. 1. A tendency toward longer activated partial thromboplastin times was noted as pregnancy proceeded, although the heparin concentration was kept constant. Table III shows that the most striking effects are insufficient treatment in the beginning of pregnancy (53% of the patients) and too high a dose at the end of pregnancy (46%). From the twenty-first to the thirty-fifth week of pregnancy, there was less need to change the heparin dose in the individual patient (Table III). The activated partial thromboplastin times and heparin concentrations are compared in Table IV. Of the 151 samples that were within the stipulated range (heparin concentration, 0.08 to 0.15 IU/ml plasma), 103 (68%) did not have a significantly prolonged activated partial thromboplastin time (i.e., >5 seconds longer than the upper normal limit).

The platelet count was monitored during the entire pregnancy and there was no depression during heparin prophylaxis. The mean level before heparin in the beginning of pregnancy was 189 ± 53 × 10^9/L, 1 week later the level was 263 ± 60 × 10^9/L, and at the last sampling (an average of 5 days before delivery), 252 ± 80 × 10^9/L. In no patient was temporary thrombocytopenia observed.

No depression of mean antithrombin III was found during heparin treatment. The mean level before the start of heparin treatment (mean, week 13) was 93% ±

10% of normal (n = 15) and the mean level before delivery was 94% ± 15% of normal (n = 26). Nevertheless, 32 of 289 samples were <80% of normal. Four patients had a single value <70% of normal. In three of 26 patients, low values (<80% of normal) were found in more than half of the samples. Two of the patients had values <70% of normal before delivery and had plasma substitution.

Comment

In an earlier study of pregnant women with previous thromboembolic complications, we used the activated partial thromboplastin time to monitor heparin administration. We then attempted a prolongation of 5 to 10 seconds above the upper normal range of activated partial thromboplastin time 3 hours after injection, during thrombosis prophylaxis. The mean amount of heparin given was then 25,000 IU/24 hours, divided into two doses. Because two of those patients had multiple fractures of the spine as a result of osteoporosis, we wanted to determine if a lower dose was sufficient to protect the women against thromboembolic complications. In this study we sought to keep the dose as low as possible and still have a measurable amount of heparin in plasma, without rethrombosis and concurrently reducing the risk for fractures of the spine. No thromboembolic or bleeding complications or fractures of the spine were observed in this study. The mean heparin dose was 16,400 IU/24 hours when the concentration of heparin was maintained at approximately 0.1 IU/ml. The results suggest that this low-dose heparin treatment is sufficient for protection against thromboembolic complications. Whether such a low dose might reduce the risk of heparin-induced osteoporosis will be evaluated in a more extensive study currently under compilation.

When a low dose of heparin is used, the activated partial thromboplastin time does not provide accurate monitoring of the heparin treatment. We therefore wanted to use a more sensitive and quantitative method in this study. The amount to be injected was therefore determined by the heparin level, measured as anti–factor Xa activity with a chromogenic substrate method, which has also been shown to reflect the antithrombotic effect.[20, 21] Our goal was to maintain the heparin peak level at approximately 0.1 IU/ml (for practical reasons, within the range 0.08 to 0.15 IU/ml). The heparin dose could be kept low because of measuring the maximal effect. If we had chosen some other time for the control of the anticoagulant effect, the heparin dose would probably have been higher.

The mean heparin dosage when the level was within the stipulated range was found to vary between 215 and 245 IU/kg body weight/24 hours during different periods of pregnancy. An increased need for heparin is observed in the second and early third trimester, with a tendency toward lower need at the end of pregnancy.

Variations among and within individuals in the anticoagulant effect of heparin are great. Two thirds of the samples within the stipulated range showed no prolongation of activated partial thromboplastin time (Table IV), which demonstrated that the activated partial thromboplastin time method is too insensitive for monitoring the anticoagulant effect of low-dose heparin treatment. Thus, if the activated partial thromboplastin time method had been used, larger amounts of heparin would have been required. However, activated partial thromboplastin time was used in connection with delivery since it reflects the total bleeding tendency and can be analyzed immediately.[22] When activated partial thromboplastin time was prolonged >10 seconds above the upper normal level, heparin was not given. Activated partial thromboplastin time was rechecked after 2 to 3 hours; 5000 IU of heparin subcutaneously or dextran was given if no prolongation was found.

No decrease in platelet count was demonstrated. Decreases in platelet count have been described in heparin treatment because of immunologic reactions[13] or could be suspected to occur because of activation and subsequent consumption. There was no mean decrease in antithrombin III, which could have occurred in the case of consumption caused by activation. Furthermore, the amount of heparin was apparently not high enough to cause a decrease in antithrombin III levels.[2, 12]

An increased fibrinopeptide A-level suggests an activation of coagulation. A slight elevation of fibrinopeptide A can be seen during the last trimester even in normal pregnancy.[23, 24] In our study, the heparin treatment seems to have been adequate since the mean fibrinopeptide A level was not higher even at the end of pregnancy compared to normal pregnancy. However, in some samples the fibrinopeptide A levels were somewhat increased, which might indicate that the heparin dosage was inadequate or that an activation had taken place during blood sampling. The latter seems possible because there were no thromboembolic complications. There was no correlation between high fibrinopeptide A levels (>4 ng/ml) and heparin concentration. A correlation could not have been expected because the heparin level reaches its maximum peak at 2 to 3 hours after injection whereas fibrinopeptide A (with a half-life of 2 to 3 minutes) could have greatly decreased during these hours. There were no samples taken for fibrinopeptide A or heparin measurements before injection. The fibrinopeptide A levels for these patients, if they had not been treated with heparin, are unknown.

The presence of lupus anticoagulant and/or cardiolipin antibodies, deficiencies of antithrombin III, and

proteins C and S should be ruled out before heparin prophylaxis is started. Experience with these abnormalities is limited. They require special consideration because of the increased risk of thromboembolic complications; thus higher doses of heparin might be necessary. In addition to anti–factor Xa activity, the platelet count, activated partial thromboplastin time, and antithrombin III should be checked shortly after the start of prophylaxis. Thereafter, it seems sufficient to control the platelet count and anti–factor Xa activity. Activated partial thromboplastin time and the platelet count should be measured just before delivery to exclude an increased bleeding tendency. Antithrombin III levels should also be analyzed; if decreased, plasma transfusions should be considered to reduce the risk for thromboembolic complications when heparin is reduced or withdrawn.

Our findings suggest that in most women without known hereditary blood coagulation defects a heparin dosage of approximately 240 IU/kg body weight per 24 hours, divided into two doses (generally 7500-10,000 IU twice daily), would be sufficient as thromboprophylaxis throughout the pregnancy. This dosage might be used if the anti–factor Xa method is not available. A recent retrospective Swedish study has shown that thrombosis prophylaxis with subcutaneous heparin during pregnancy resulted in a recurrence of thrombosis equal to that which occurred during no thromboprophylaxis. The patients with recurrence of thromboembolic complications during heparin prophylaxis were treated with subcutaneous heparin, 5000 IU twice daily.[25] Because the need for heparin varies among different patients, an individualized treatment would be ideal. We suggest the anti–factor Xa activity method for monitoring because it is the most sensitive current method of heparin analysis. On the basis of our experience, the patients should be checked once a month after the correct dose has been established. More frequent controls are needed during the third trimester. Whether this heparin regimen will further minimize the risk of fractures as a result of heparin-induced osteoporoses is unknown.

We thank Dr. Ulf Hansson for assistance with the statistical analysis and Mrs. Hjördis Johannesson for performing the heparin determinations.

Early pregnancy glycosylated hemoglobin, severity of diabetes, and fetal malformations

Michael J. Lucas, MD, Kenneth J. Leveno, MD, M. Lynne Williams, RN, Philip Raskin, MD, and Peggy J. Whalley, MD

Dallas, Texas

Total percent glycosylated hemoglobin (A_{1a+b+c}) was measured before 16 weeks' gestation in 105 insulin-treated diabetic women enrolled for prenatal care at Parkland Memorial Hospital. Seventy-three of the infants were normal, 14 had malformations, and there were 18 spontaneous abortions. The mean glycosylated hemoglobin level for the entire study group was 9.2%, compared with 9.4% for those pregnancies ending in abortion, 8.9% for those resulting in normal infants, and 10.3% when malformations occurred. The mean glycosylated hemoglobin value for women delivered of normal infants was significantly lower than the mean of those with malformed infants. Ten of the 14 malformations occurred in mothers whose early pregnancy values exceeded the mean of the entire study group. There was also an association between malformations and White classification of maternal diabetes since 10 of the 14 fetal anomalies occurred in women assigned to White Classes C, D, F, H, and R. When the distribution of malformations was analyzed according to both glycosylated hemoglobin level and White Class, there was evidence of an interaction to suggest that hyperglycemia increases the relative risk of fetal malformations when associated with maternal diabetes of longer duration and/or with vascular complications. (AM J OBSTET GYNECOL 1989;161:426-31.)

Key words: Glycosylated hemoglobin, diabetic pregnancy, malformations

A heterogeneous group of skeletal, cardiovascular, neurologic, and urogenital malformations has been estimated to occur two to five times more frequently in pregnancies complicated by diabetes. The cause has been attributed to a variety of factors that include hyperglycemia, diabetic microangiopathy and vascular insufficiency, hypoglycemia, genetic predisposition, and even use of insulin.[1]

In 1978, Leslie et al.[2] reported an association between hyperglycemia as reflected by elevated glycosylated hemoglobin levels at the initial visit in pregnancy and fetal malformations. Miller et al.[3] subsequently reported measurement of hemoglobin A_{1c} before 14 weeks' gestation in 113 diabetic women and found it significantly elevated in the 14 pregnancies that resulted in malformed infants.

A number of descriptive studies of malformations linked to maternal diabetes have also suggested a relationship to White's classification.[4, 5] The observation of increased malformation rates related to advanced White's classification may indicate that the variables used in this classification that include age at onset of diabetes, duration of disease, and microvascular complications also impact normal embryonic development. Alternatively, it is also possible that diabetic women with advanced disease may have higher average glycemia, and that relative hyperglycemia is the only causal factor in fetal malformations.

In this report we describe a prospective investigation of total glycosylated hemoglobin measured before 16 weeks' gestation in 105 insulin-treated women. Early pregnancy maternal hyperglycemia as reflected by elevated glycosylated hemoglobin levels was associated with fetal malformations. However, this effect of maternal hyperglycemia was also related to White's Class, an index of the duration and severity of diabetes. This suggests an interaction between hyperglycemia and these factors in the cause of fetal malformations in pregnancies complicated by diabetes.

Material and methods

Total glycosylated hemoglobin was measured in all pregnant insulin-treated diabetic women initially seeking prenatal care at Parkland Memorial Hospital before 16 weeks' gestation. Women with diabetes antedating pregnancy were classified according to White during in-hospital evaluations that included assessment of renal function and retinal examinations. Those women not diagnosed as diabetic before the index pregnancy, but who were treated with insulin because of fasting

hyperglycemia discovered before enrollment in the study, were separately classified as having gestational diabetes.

Hemoglobin A_{1a+b+c} was determined by ion exchange chromatography with the use of prepacked microcolumns (Quick-column, Helena Laboratory, Beaumont, Tex.) after twice washing the erythrocytes and overnight incubation at 23° C to remove the labile fractions.[6] Hemoglobin A_{1c} was also measured in 58 of the 105 women. This subfraction of glycosylated hemoglobin is frequently reported as an index of prior glycemia in diabetic patients, but was not available early in our study. However, the Pearson's correlation coefficient between the two glycohemoglobin measurements was 0.965. Preprandial plasma glucose levels were measured at 7 AM, 11 AM, 4 PM, and 9 PM during the day of glycosylated hemoglobin measurement and the mean plasma glucose concentration was calculated for each woman.

Infants of insulin-treated diabetic women were admitted to the Special Care Nursery for careful glucose monitoring. Malformations included those clinically diagnosed before discharge of the infant. To reduce the possibility of ascertainment bias, newborn examinations were performed by the pediatric staff without knowledge of the patient's enrollment into the study cohort. Assessment of the spontaneous abortions for malformations was precluded by maceration or incomplete availability of tissue for examination. Chromosomal analysis of aborted tissues was not performed.

Statistical analyses included Fisher's exact test of probability, log-likelihood χ^2, and Student's t test or analysis of variance when appropriate.

Results

Between February 1980 and July 1985, 105 consecutive insulin-treated women were enrolled for prenatal care before 16 weeks' gestation and had glycosylated hemoglobin levels measured. The range of gestational age at entry into the study was from 6 to 16 completed weeks' gestation. There was no apparent relationship between disease classification and gestational age when they were first seen. Twenty-three (22%) of these women were classified as having gestational diabetes because fasting hyperglycemia (fasting plasma glucose level >105 mg/dl; mean, 145 mg/dl) was first diagnosed during the index pregnancy at the time of presentation for prenatal care. The remainder of the women with diabetes antedating pregnancy were classified according to White as follows: Class A (n = 4), Class B (n = 27), Class C (n = 25), Class D (n = 18), and Classes F, H, and R (n = 8).

Total glycosylated hemoglobin (A_{1a+b+c}) was also measured in 14 nondiabetic normal women at a similar gestational age; their mean value was 6.0% (range, 5.0% to 6.9%). In contrast, the mean hemoglobin A_1 of the 105 study patients was 9.2% (range, 5.2% to 14.2%). The mean preprandial plasma glucose concentration on the day of hemoglobin A_1 determination for this group was 151 ± 51 mg/dl (SD). The correlation coefficient between the initial glycosylated hemoglobin and mean preprandial plasma glucose was 0.59 and is similar to other reports on the correlation between same-day measures.[7]

Table I. Pregnancy outcomes of 105 insulin-treated diabetic women according to glycosylated hemoglobin level determined before 16 weeks' gestation

Pregnancy outcome	*Pregnancies*		*Glycosylated hemoglobin (%) (mean ± SD)*
	No.	*%*	
Spontaneous abortion	18	17	9.4 ± 2.3
Malformed infant	14	13	10.3 ± 1.9*
Normal infant	73	70	8.9 ± 2.3
TOTAL	105	100	9.2 ± 2.3

*Comparison of mean A_1 levels between malformed and normal infants, p = 0.05 (Student's t test).

The 105 pregnancies studied were divided into three major outcome groups as shown in Table I. Eighteen women spontaneously aborted. Their mean hemoglobin A_1 level was 9.4% ± 2.3% (SD), which was not significantly different from the mean A_1 hemoglobin values of those pregnancies resulting in malformed (10.3% ± 1.9%) or normal (8.9% + 2.3%) infants (analysis of variance, F probability = 0.125). The mean ± SD gestational age at glycosylated hemoglobin determination for those pregnancies that ended in abortion was 9.8 ± 2.8 weeks compared with 11.4 ± 2 weeks for pregnancies that resulted in malformed infants and 11.6 ± 2.7 weeks for women who were delivered of normal infants. There was no statistical difference in the latter two groups in gestational age at the time of initial examination. Maternal age, race, and previous pregnancy outcomes for the three outcome groups did not differ significantly.

The 18 pregnancies that resulted in abortions were equally divided between missed and spontaneous abortions. There was no significant difference in glycosylated hemoglobin or maternal class of diabetes between these two subgroups. Analysis of the distribution of the abortions according to glycosylated hemoglobin levels by arbitrarily dividing the A_1 range into thirds revealed no association of this outcome with the degree of early pregnancy glycemia. Specifically, six (16%) spontaneous abortions occurred with glycosylated hemoglobin levels ≤8.0%, 8 (17%) with levels from 8.1 to 11.0%, and 4 (20%) in pregnancies with levels >11%. Similarly, analysis of the pregnancies that ended in abortion ac-

cording to classification of maternal diabetes showed no significant correlation.

Excluding those pregnancies that ended in abortion as a group of undetermined malformation outcome, 14 (16%) of the remaining 87 diabetic women were delivered of malformed infants. Eight infants had major malformations that included anencephaly ($n = 2$), hydrocephalus ($n = 1$), encephalocele ($n = 1$), sacral agenesis ($n = 1$), micropenis-hypospadias ($n = 1$), and ventricular septal defects ($n = 2$), one of which was associated with pulmonic stenosis. Minor malformations were diagnosed in six infants and included polydactyly ($n = 2$), partial limb atrophy ($n = 2$), supernumerary nipples ($n = 1$), and preauricular skin tags ($n = 2$). Two infants with testicular hydroceles and one with undescended testes were considered normal variants. The mean glycosylated hemoglobin levels of women delivered of infants with either major or minor malformations were not significantly different (i.e., 10.29% ± 1.8% vs. 10.27% ± 2.7%, respectively). The mean ± SD glycosylated hemoglobin level of the 73 women whose pregnancies resulted in normal infants was 8.9% ± 2.3% compared with 10.3% ± 1.9% for those delivered of infants with major or minor malformations ($p = 0.05$). Table II shows a stratification of pregnancies that progressed beyond abortion according to maternal glycosylated hemoglobin level with the malformation rate for each level indicated. There was a statistically significant distribution ($p = 0.05$) of malformation above the A_1 mean of 9.2%; 10 of the 14 malformations occurred in 42 women whose levels exceeded the mean, compared with four malformations in the 45 women with levels below the mean. The distribution of fetal malformations according to classification of maternal diabetes in the same 87 women is provided in Table III. A significant ($p < 0.05$) increase in malformations was observed in women whose diabetes was diagnosed at ≤19 years of age, those who had diabetes for ≥10 years, and those with vascular complications (White's Classes C, D, F, H, and R).

The relationship between maternal glycosylated hemoglobin level and classification of diabetes was analyzed independently of outcome. Women assigned to White's Classes C, D, F, H, and R were found to have significantly higher hemoglobin A_1 levels early in pregnancy. The mean ± SD glycosylated hemoglobin was 8.8% ± 2.3% for those women who were classified as gestational diabetics or assigned to Classes A and B compared with 9.7% ± 2.1% for those in Class C or greater ($p = 0.05$). Because of this correlation between glycosylated hemoglobin and class of diabetes, the distribution of malformations was tabulated according to both variables; the results are shown in Table IV. There was a tendency for the malformation rate to increase according to both class of maternal diabetes and glycosylated hemoglobin level. The effect of higher A_1 levels was more pronounced in women with advanced diabetes. Log-likelihood χ^2 analysis revealed that the statistically significant distribution of malformations according to A_1 level was attributable primarily to the strength of the association in those women with diabetes of longer duration and/or increased severity. This finding indicates an interaction between the two indices (A_1 and class) in association with the rate of malformation. Major malformations accounted for most of this observed interaction.

The major malformation rate in those diabetic pregnancies that progressed beyond abortion was roughly equivalent according to either the severity of diabetes or glycosylated hemoglobin level when considered separately. Specifically, there was a 17% major malformation rate in women of more advanced diabetes class ($p = 0.02$) and a 14% major malformation rate in those with glycosylated hemoglobin levels above the mean ($p = 0.125$). The rate remained 14% if the upper two thirds of the glycosylated hemoglobin range were considered. An improved discrimination resulted when both disease severity and glycosylated hemoglobin level were considered simultaneously. The major malformation rate was 25% (6 of 24) in those with both ad-

†Statistical evaluation of distribution of malformations according to A_1 level for class grouping: Log-likelihood χ^2 distribution of malformations × A_1 ($p < 0.05$).

vanced diabetes and an A_1 level above the mean of 9.2%. In contrast, there were no major malformations in the 18 pregnancies with an A_1 level >9.2% within the less severe classes of diabetes. Log-likelihood χ^2 analysis of the distribution of major malformations within these four groups (two class categories and two A_1 strata) was also statistically significant ($p < 0.02$, Table V). The finding of a gradient rate of both major and all malformations according to A_1 level in the advanced diabetes group supports the specificity of the interaction.

Table V. Major malformations

Hemoglobin A_1	*Class of diabetes*	*No. of malformations per No. of pregnancies**

$A_1 \geq 9.2\%$	Classes A, B, G	0/18 (0%)
	Class ≥ C	6/24 (25%)

*Analysis of the distribution of major malformations within the four categories shown: $p = 0.017$ (log-likelihood χ^2).

Comment

The increased risk of malformations in infants of insulin-treated diabetic mothers is evident in this series, with an overall malformation rate of 16% in those pregnancies that progressed beyond spontaneous abortion. Analysis for possible teratogenic mechanisms suggests that maternal hyperglycemia during organogenesis as reflected by glycosylated hemoglobin levels is clearly a factor. However, increasing severity of diabetes, as indicated by the White classification of diabetes during pregnancy, appears to be at least a cofactor in the increased rate of malformations.

Glycohemoglobin has been established as a reliable index of prior glycemia.[7] The finding of increased malformation rate in association with elevated glycosylated hemoglobin implicates early pregnancy hyperglycemia as a causative factor. Miller et al.[3] demonstrated a relationship between early pregnancy maternal hyperglycemia and fetal malformations. They observed that women who were delivered of infants with major anomalies had significantly higher levels of hemoglobin A_{1c} during the first trimester. Similar results have been reported by other investigators.[8] Importantly, Mills et al.[9] have shown that organogenesis for all the sites in which congenital anomalies linked to diabetes are most common are essentially complete within the first 6 weeks of gestation. These studies provide circumstantial evidence that hyperglycemia during critical weeks of organogenesis plays a teratogenic role in the excess malformations characteristic of pregnancies complicated by diabetes.

Experimental studies support the concept of hyperglycemia as a teratogenic factor. Hyperglycemia induced in laboratory animals during the developmental period of gestation has been shown to increase malformation rates. Conversely, glycemic normalization has been shown to obviate that risk.[10] In a large interventional study in a well-defined human population of pregnant diabetics, Fuhrmann et al.[11] have demonstrated that strict periconceptual glycemic control abolishes the increase in malformations otherwise observed. Jovanovic and Jovanovic[12] also observed no malformations in infants of a group of diabetic mothers with microvascular complications in whom strict pregestational glycemic control was established; they used glycosylated hemoglobin "normalcy" to confirm adequate control.

Our finding of a relationship between malformation rate and the White classification of severity of diabetes during pregnancy as an independent variable is also consistent with previous reports.[4, 11, 13] In a study of 1452 pregnancies in Copenhagen between 1926 and 1972, Pedersen[5] reported a 4.9% incidence of malformations in White Classes A, B, and C compared with 13.7% in Classes D and F. Similarly, Soler et al.[4] reported that among 701 infants born to diabetic women in Bir-

mingham, England, mothers whose diabetes began before 20 years of age had a higher incidence of fetal malformations compared with those whose diabetes was diagnosed at an older age. In a more recent study from Copenhagen, the risk of fetal malformations among 99 insulin-dependent diabetic women examined by ultrasonographic scanning in the seventh and fourteenth weeks of pregnancy was significantly higher in White's Classes D and F compared with the less severe classes of A, B, and C.[14] Comess et al.[15] also observed a small subpopulation among Pima diabetic mothers characterized by onset of diabetes at an early age who were at particular risk for malformed infants. However, not all investigators have found severity or duration of diabetes to significantly influence malformation rates.[3]

It must also be considered that a confounding relationship may exist between hyperglycemia and severity of diabetes, with fetal malformations resulting from greater hyperglycemia in those with more severe disease. Indeed, a correlation between glycosylated hemoglobin and severity of diabetes during pregnancy has been reported.[7] Our finding of a significant glycosylated hemoglobin difference between the two class groups used in our analysis further suggests the presence of such a confounding relationship. However, the interaction we observed between class and A_1 level in association with the relative malformation rate implies that both variables are related to risk, and this has further etiologic implications.

We can only speculate as to why hyperglycemia would have a more potent effect on malformation occurrence in women with disease of longer duration and/or increased severity. A model with hyperglycemia as a "necessary but insufficient" teratogen might best fit the data. For instance, it might be that a metabolic consequence of hyperglycemia is the etiologic culprit, perhaps more likely produced in those with prolonged, advanced diabetes. This would explain the lack of major malformations observed in our 18 cases with high indices of early hyperglycemia but with recent onset of uncomplicated diabetes. Although this model might seem to contradict aforementioned studies, it has been difficult to experimentally isolate hyperglycemia from other variables.[1] Specific products or indirect effects of hyperglycemia such as disturbed glycolysis and arachidonic acid metabolism,[16] specific ketones,[17] and disturbances of insulin-like growth factors[18] have been implicated as embryopathic effectors. Identification of a specific metabolic disturbance associated with hyperglycemia that accurately predicts malformation occurrence would certainly be the ideal marker of risk.

The specific risk factor associated with disease classification is also unidentified. For instance, it is possible that ketosis-prone diabetics (type I) are those more susceptible to the teratogenic effects of hyperglycemia. Type I disease is very likely associated with the advanced class group used in this analysis. The multifactorial nature of malformation risk in association with diabetes is emphasized in the recent report by Mills et al.[19] that describes a lack of relationship between early measures of glycemia and malformation outcome in prospectively followed "insulin-dependent" diabetics. Unfortunately, no analysis by disease classification was reported; because the early enrollment groups had a lower malformation rate than those enrolled late, they nonetheless concluded that relative glycemia cannot be discounted as a risk factor.[19]

If hyperglycemia is a necessary cofactor as a teratogen in diabetes, then it is tempting to use glycohemoglobin in individual risk-factor analysis. However, a direct application of study data can result in some confusion, as exemplified in the use by Jovanovic and Jovanovic of the median A_{1c} value of 8.5% (as determined by Miller et al.[3]) as both a threshold of risk and a limit of "normalcy."[12] Our method of analysis was similar to that of Miller et al., yet our mean A_1 value of 9.2% projects to an A_{1c} value of 7.2% on our regression line between the two measures. This difference might be a result of laboratory technique, study population, or both, but in any case should prompt caution in the use of a specific glycosylated hemoglobin level as an absolute threshold for risk estimation. Furthermore, if "normalcy" is the glycohemoglobin range in pregnant women without diabetes, the highest measure in our study was the equivalent of an A_{1c} value of 5.5%. Although there were no malformations in our series in the 15 diabetic women with glycohemoglobin within this normal range, a clear threshold for malformation occurrence above this point is not apparent in the data. The tendency of malformation rate to increase with rising glycohemoglobin measure was attributable to the distribution within the more severe class group. However, we caution that relatively small numbers occur in each subcategory in this analysis. Therefore the results cannot be reasonably extrapolated except to suggest general trends in relative risk. For example, it would be a mistake to conclude from our results that we are implying that a Class B diabetic is safe from the occurrence of malformation.

In conclusion, it is clear that teratogenic mechanisms are operative during pregnancies that are complicated by diabetes but the mechanism(s) may be more complex than a simple relationship to relative glycemia. Awareness of the interaction between severity of diabetes and early glycohemoglobin measure might improve relative risk estimates in pregnant diabetics, but we emphasize appropriate caution in such clinical applications.

Predictive value of increased plasma levels of fibronectin in gestational hypertension

Véronique Ballegeer, MD,[a] Bernard Spitz, MD,[b] Lena Kieckens,[a] Huberte Moreau,[a] André Van Assche, MD,[b] and Désiré Collen, MD, PhD[a]

Leuven, Belgium

Blood pressure, proteinuria, and plasma fibronectin and plasminogen activator inhibitor-1 levels were measured in 120 apparently healthy normotensive primigravid women during the first, second, and third trimesters of pregnancy and 2 days post partum. Thirty-two women developed hypertension (diastolic blood pressure ≥90 mm Hg) that in 17 women was associated with proteinuria (>0.3 gm/day). Fibronectin levels were 83% ± 22% of normal (mean ± SD) during the first trimester and 75% ± 20% at term in the healthy women but increased from 94% ± 36% to 187% ± 36% in the women who developed gestational hypertension (with or without proteinuria) ($p < 0.0001$). Plasminogen activator inhibitor-1 levels increased from 26 ± 19 ng/ml to 110 ± 86 ng/ml in healthy women and from 32 ± 35 ng/ml to 290 ± 90 ng/ml in hypertensive women ($p < 0.0001$). Increased levels of fibronectin at 25 to 36 weeks of pregnancy (≥mean + 2 SD of the healthy women, or >140%) were found in 31 of the 32 women with gestational hypertension with or without proteinuria and in 5 of the 88 healthy women (sensitivity 96%, specificity 94%). Fibronectin levels increased 3.6 ± 1.9 weeks earlier than the onset of hypertension and/or proteinuria. Increased levels of plasminogen activator inhibitor-1 at 25 to 32 weeks (≥280 ng/ml) were found in 16 of the 32 women who developed gestational hypertension with or without proteinuria and in 4 of the 88 healthy women (sensitivity 50%, specificity 95%). We conclude that increased fibronectin levels are the best predictor of gestational hypertension with or without proteinuria and that its level in plasma increases several weeks before the development of hypertension. (Am J Obstet Gynecol 1989;161: 432-6.)

Key words: Fibronectin, plasminogen activator inhibitor-1, preeclampsia, gestational hypertension

Fibronectins are large adhesive glycoproteins (440 kilodaltons) present in many tissues and in most body fluids.[1] The soluble form, usually referred to as plasma fibronectin, is present at a rather high concentration (300 μg/ml) in plasma. The insoluble form, called cellular fibronectin, is produced by fibroblasts, endothelial cells, macrophages, and blood platelets and is a widespread component of connective tissue and basement membranes. A variety of functions have been ascribed to fibronectin, including roles in opsonization, cell adhesion, cell motility, tissue repair, and coagulation.[1-4] Increased levels of fibronectin in plasma have been observed in established gestational proteinuric hypertension.[5-8]

The decreased fibrinolytic activity in patients with gestational proteinuric hypertension[9] has been attributed to an increased plasma level of both plasminogen activator inhibitor-1 (PAI-1) and plasminogen activator inhibitor-2 (PAI-2).[10-12] PAI-1 is secreted by endothelial cells, fibroblasts, blood platelets, and hepatocytes. PAI-1 levels increase steadily after the twentieth week of pregnancy.[11] PAI-2 is produced by placental tissue, it is undetectable in normal plasma but increases markedly during pregnancy.[11]

In this study we investigated the time course of changes in plasma levels during pregnancy of several plasma proteins including fibronectin and PAI-1 in an effort to correlate changes in their concentration with the development of gestational hypertension with or without proteinuria.

Material and methods

Patients. A total of 120 apparently healthy normotensive primigravid women selected from 129 consecutive primigravid women seen at the outpatient clinic of the Department of Obstetrics by B. S. between September 1987 and January 1988 were prospectively included in the study after giving informed consent. The nature of the study was explained in detail. None of the subjects who were requested to participate in the study declined. The blood pressure was measured in

N, Normotensive women (n = 88); *H*, hypertensive women (n = 32); *AT-III*, antithrombin III. Data represent mean ± SD. Numbers within parentheses indicate number of subjects with values >mean + 2 SD of 88 normotensive primigravid women for fibronectin and >90 mm Hg for diastolic blood pressure.

the sitting position. The diastolic pressure was defined as the pressure at which a Korotkoff phase V was obtained. Nine patients with a diastolic blood pressure >90 mm Hg were not entered into the study. Blood pressure was measured before 20 weeks of pregnancy, at 4-week intervals between 20 and 32 weeks, at 2-week intervals between 32 and 36 weeks, and at weekly intervals between 36 weeks and delivery.

Gestational hypertension was defined as a diastolic blood pressure of ≥90 mm Hg on at least two occasions during the second half of pregnancy in a previously normotensive woman. Gestational proteinuric hypertension (or preeclampsia) was defined as increased diastolic blood pressure and ≥0.3 gm proteinuria/day (as defined by the International Society of Study for Hypertension in Pregnancy).[13]

Management of the subjects was determined on the basis of clinical signs and blood pressure only and was not altered on the basis of results of blood analyses. The subjects were asked to refrain from aspirin intake during the study.

Methods. Blood samples were taken four times during pregnancy: before 20 weeks, between 20 and 30 weeks, either at 31 to 35 weeks or 36 to 40 weeks, and 2 days post partum. When increased levels of fibronectin were found, additional blood samples were taken at weekly intervals for monitoring its evolution, but the first positive sample was used in the calculations. Blood was obtained by venipuncture, anticoagulated with buffered citrate (nine parts of blood were mixed with one part 0.1 mol/L sodium citrate (citric acid, pH 4.5 and pH 7.5) and centrifuged for 15 minutes at 3000 *g* at 4° C. The plasma samples were stored at −20° C and analyzed within 14 days.

Fibronectin and von Willebrand factor antigen were measured by Laurell immunoelectrophoresis,[14] with commercial antisera from Behringwerke (Marburg/Lahn, West Germany) and Nordic (Tilburg, The Netherlands), respectively. Concentrations were expressed in percentage of a normal plasma pool. PAI-1,[15] tissue plasminogen activator (t-PA),[16] and fibrin fragment D-dimer[17] levels in plasma were determined with specific enzyme-linked immunosorbent assays. PAI-2 levels were determined with an immunoradiometric assay[18] with reagents provided by Dr. E. K. O. Kruithof (Centre Hospitalier Universitaire du Vaudois, Lausanne, Switzerland). Antithrombin III was determined with a chromogenic substrate assay (Kabi-Vitrum, Brussels, Belgium). Statistical analysis was performed by analysis of variance to assess the changes over time of the various parameters using the SAS program ANOVA (SAS Institute GmbH, Heidelberg, Federal Republic of Germany).

Results

Thirty-two of the 120 healthy initially normotensive primigravid women developed gestational hypertension, which in 17 was associated with proteinuria. In two women the first diastolic blood pressure ≥90 mm Hg was observed between 21 and 30 weeks of preg-

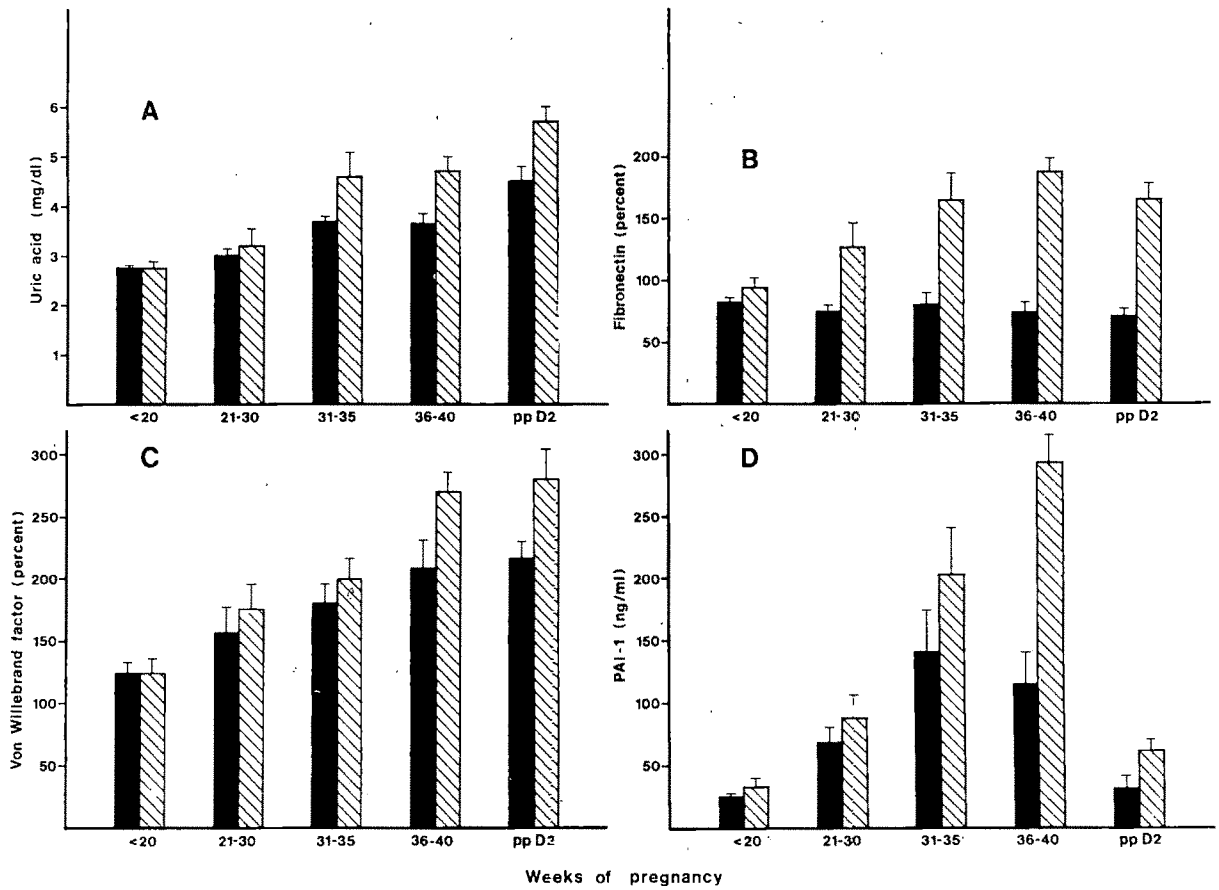

Fig. 1. Plasma levels of uric acid **(A)**, fibronectin **(B)**, von Willebrand factor **(C)**, and PAI-1 **(D)** during pregnancy in 88 normotensive women *(solid bars)* and in 32 women with gestational hypertension *(hatched bars)*. Results in *columns* represent means and *bars* are SEM.

nancy, in 1 between 31 and 35 weeks, in 11 women between 36 and 38 weeks, and in 18 women between 39 weeks and delivery. The mean diastolic blood pressure of the 32 primigravid women with gestational hypertension at the onset of labor was 150 ± 7 mm Hg systolic and 96 ± 6 mm Hg diastolic. Table I summarizes the results of blood pressure, uric acid, and plasma protein determinations in the 32 women who developed gestational hypertension with or without proteinuria, compared with the 88 women who remained normotensive.

In both the normotensive and hypertensive groups PAI-1, PAI-2, von Willebrand factor, and fragment D-dimer levels increased significantly during pregnancy. Significant differences between the normotensive and hypertensive groups were observed for uric acid, fibronectin, von Willebrand factor, t-PA, and PAI-1, which all increased more in the hypertensive group. The p values for all these differences were <0.01. The results of uric acid, fibronectin, von Willebrand factor, and PAI-1 are summarized in Fig. 1. No significant differences between the groups or changes during pregnancy were observed for antithrombin III levels. Multivariate analysis of results obtained at 36 to 40 weeks in the hypertensive group revealed significant correlations ($p < 0.01$) between fibronectin level and diastolic blood pressure ($r = 0.66$), uric acid ($r = 0.50$), von Willebrand factor ($r = 0.49$), and PAI-1 ($r = 0.60$). PAI-1 levels correlated with diastolic blood pressure ($r = 0.82$) and t-PA levels ($r = 0.60$).

The most significant differences between the normotensive and hypertensive groups were observed for the fibronectin and PAI-1 levels, which were already significantly more increased in the hypertensive group at 21 to 30 weeks' gestation ($p < 0.0001$), whereas at that time the differences in von Willebrand factor, t-PA, and uric acid levels were less pronounced. When increases in the fibronectin and PAI-1 levels were used as predictors of the development of gestational hypertension, and an increase of more than 2 SDs above the mean of the normotensive group (≥140% and 280 ng/ml, respectively) was used as the cutoff point, the results summarized in Table II were obtained. None of the 13 subjects with an increased fibronectin level at 31 to 35 weeks had returned to levels <140% when mea-

Table II. Frequency of increased levels of fibronectin and PAI-1 in normal and hypertensive primigravid women

Group	n	Fibronectin		PAI-1	
		Increased	Normal	Increased	Normal
Gestational hypertension	32	31	1	16	16
Control subjects	88	5	83	4	84

Upper limit of normal was defined as mean value + 2 SD of control group. This corresponded to 140% of normal for fibronectin and 280 ng/ml for PAI-1.

sured at 36 to 38 weeks. Increased fibronectin levels predicted the development of gestational hypertension with a sensitivity of 96% and a specificity of 94%. Increased PAI-1 levels predicted the developed of gestational hypertension with a sensitivity of only 50% and a specificity of 95%.

With use of an alternative definition of gestatinoal hypertension as an increase in systolic blood pressure of >30 mm Hg and of diastolic blood pressure of >15 mm Hg, two of the four subjects with an elevated fibronectin level but a diastolic blood pressure of <90 mm Hg would have been allocated to the group with gestational hypertension instead of the normal group. When the onset of the increase in fibronectin level was correlated with the first observation of hypertension, results were obtained as illustrated in Fig. 2. The increase in fibronectin level consistently preceded the increase of the diastolic blood pressure by an average of 3.6 ± 1.9 weeks.

Table III summarizes the results of diastolic blood pressure and fibronectin levels in the 32 women with gestational hypertension, subdivided in groups with or without proteinuria. No significant differences between the subgroups were observed.

Comment

Gestational proteinuric hypertension (preeclampsia) is a primary cause of perinatal mortality and morbidity. Early recognition and treatment with bed rest and aspirin favorably influence outcome.[19] The availability of simple predictors of the subsequent development of gestational hypertension might allow preventive treatment and further improve outcome. A close correlation between increased fibronectin levels and gestational proteinuric hypertension (preeclampsia) has been reported by several authors.[5-8]

Therefore we performed a prospective study in 120 apparently healthy initially normotensive primigravid women to correlate changes in blood pressure and proteinuria with uric acid and with several plasma proteins. As expected, several proteins increased during pregnancy in both groups, including von Willebrand factor, PAI-1, PAI-2, and fibrin fragment D-dimer, whereas before the thirtieth week fibronectin and PAI-1 increased significantly more in the hypertensive group than in the normotensive group. If an increase of fibronectin >140% of normal was used as the cutoff point, subsequent development of gestational hypertension within an average of 3.6 ± 1.9 weeks could be predicted with a sensitivity and specificity of approximately 95%. PAI-1 levels also increased early and more extensively in women with subsequent gestational hypertension, but this index had less predictive value, because PAI-1 levels also increased in the normotensive group.

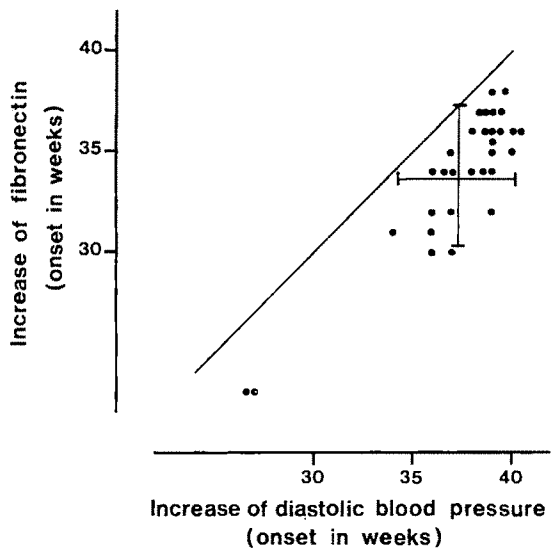

Fig. 2. Correlation between time of onset of increase in fibronectin level (>140%) and of increase of diastolic blood pressure (>90 mm Hg). Data represent duration of pregnancy at time when the first increase in fibronectin (>140%) or in diastolic blood pressure (>90 mm Hg), respectively, was observed in the subjects developing gestational hypertension. Increase in fibronectin level preceded increase in blood pressure by average of 3.6 ± 1.9 weeks (mean ± SD). Horizontal and vertical *bars* represent interval from mean − SD to mean + SD of duration of pregnancy at which increased values were first obtained.

Fibronectin levels may change in association with several disease states. Levels decrease in cases of liver insufficiency, disseminated intravascular coagulation, respiratory distress syndrome, sepsis, and polytrauma and increase in patients with rheumatoid arthritis.[20, 21] None of these diseases occurred in the subjects studied.

We also studied eight pregnant women with chronic hypertension at 31 to 35 weeks of pregnancy and found a normal fibronectin level (data not shown). This suggests that hypertension per se is not associated with increased fibronectin levels during pregnancy.

In conclusion, our results suggest that increased plasma fibronectin levels may be a highly sensitive and

Table III. Diastolic blood pressure and fibronectin levels in 32 primigravid women with gestational hypertension, subdivided according to presence or absence of proteinuria

Parameter	*Proteinuria*	*n*	*Weeks of pregnancy*				*At delivery*
			<20	*21-30*	*31-35*	*36-38*	
Diastolic pressure (mm Hg)	Yes	17	66 ± 8	76 ± 7	79 ± 13	91 ± 5	96 ± 6
	No	15	68 ± 6	71 ± 5	70 ± 8	83 ± 5	92 ± 2
Fibronectin (%)	Yes	17	101 ± 36	150 ± 93	170 ± 96	190 ± 32	—
	No	15	84 ± 22	106 ± 32	150 ± 26	180 ± 52	—

specific predictive test for (proteinuric) gestational hypertension. The index (cutoff point of ≥140% of normal) used in this study was derived from and reapplied to the same patient population and set at a level that allowed maximal separation between normal and hypertensive patients. Therefore prospective studies with the use of this same index are required to confirm its high sensitivity and specificity.

We thank Mr. De Wel (Department of Medische Informatica, K.U., Leuven, Belgium) for his help with the statistical analysis and Dr. E. K. O. Kruithof (Department of Haematology, Centre Hospitalier Universitaire du Vaudois, Lausanne, Switzerland) for providing all essential reagents for the PAI-2 assay.

Zinc, cadmium, and hypertension in parturient women

Noam Lazebnik, MD, Betty R. Kuhnert, PhD, and Paul M. Kuhnert, PhD, MD
Cleveland, Ohio

Zinc deficiency and cadmium toxicity have both been implicated in hypertension during pregnancy. The goals of this study were twofold: first, to assess the different zinc indices (plasma, red blood cell zinc, heat-labile alkaline phosphatase, and placental zinc) in normotensive and hypertensive parturients to determine whether they are altered in the different types of hypertension that occur during pregnancy; second, to assess whole-blood cadmium and placental cadmium with regard to hypertension and zinc status. Patients were diagnosec as having chronic hypertension or preeclamptic toxemia and were then further divided into groups on the basis of smoking status. Each patient was matched with a normal control subject based on age, parity, and smoking status. Forty-three hypertensive patients and their matched control subjects were studied. No differences were found in the various zinc indices between chronic hypertensive parturients and normal control subjects. However, in parturients with preeclamptic toxemia, the plasma zinc level was 19% lower than in control subjects ($p < 0.02$); these patients had the lowest plasma zinc level of the three groups. Placental zinc was also 12% lower in patients with preeclamptic toxemia than in control subjects ($p < 0.04$). Whole-blood cadmium and placental cadmium levels did not differ between control subjects or hypertensive patients. However, a significant positive correlation was found between whole-blood cadmium and plasma zinc levels in preeclamptic toxemia ($r = 0.53$; $p < 0.05$). The results support a marginal zinc deficiency in parturients with preeclamptic toxemia but not in those with chronic hypertension. The role of cadmium in the cause of preeclamptic toxemia remains unclear. (Am J Obstet Gynecol 1989;161:437-40.)

Key words: Zinc, cadmium, hypertension, pregnancy

Several previous studies have related abnormally low zinc levels to hypertension during pregnancy.[1-4] Some of these studies included only those patients with preeclamptic toxemia,[2-4] whereas others did not specify the type of hypertensive disorder.[1] Most studies used the maternal plasma zinc level as the sole indicator of zinc status. Recently, Adeniyi[4] reported lowered maternal plasma zinc and leukocyte zinc levels in some patients with preeclamptic toxemia.

Lazebnik et al.[5] and Kuhnert et al.[6,7] have shown that some indices of zinc status depend on smoking, age, or parity. These important factors were not taken into consideration in the early studies of zinc and hypertension. Moreover, other indices of zinc status such as red blood cell zinc, placental zinc, or zinc-dependent enzymes have not been adequately studied in hypertensive parturients.

There is also a need to study the possible role of cadmium in hypertension during pregnancy.[8] The strongest evidence to link cadmium with hypertension is derived from animal studies[2] and tissues at autopsy from hypertensive patients.[9] Cadmium toxicity has been hypothesized as being responsible for preeclamptic toxemia during pregnancy.[2] The question of whether pregnant patients are more sensitive to the toxic effect of cadmium or whether there are higher levels of cadmium in the blood or placenta of these patients has not been answered. Recent reports of interactions between cadmium and zinc in the placenta of normal patients[6,7] suggest that these questions need to be addressed in hypertensive patients.

Our study had two goals. First, we wanted to assess the different zinc indices (plasma zinc, red blood cell zinc, heat-labile alkaline phosphatase, and placental zinc) in normotensive and hypertensive parturient women to determine whether they are altered in the different types of hypertension in pregnancy. Second, we wanted to assess whole-blood cadmium and placental cadmium levels with regard to hypertension and zinc status.

Material and methods

Patients and collection of samples. Eighty-six women were studied at the time of delivery. All were given a full explanation of the purpose, potential benefits, and hazards of the study in order to obtain appropriate informed consent. The study was approved by the human investigation committee of Cleveland Metropolitan General Hospital.

Table I. Indices of zinc status with regard to type of hypertension and smoking

	Plasma zinc (μg/dl) (mean ± SD)	*Red blood cell zinc (μg/dl) (mean ± SD)*	*Alkaline phosphatase (units/100 ml) (mean ± SD)*	*Placental zinc (μg/gm) (mean ± SD)*
Nonsmokers				
Preeclamptic toxemia (n = 17)	42 ± 10*	1231 ± 125	5.9 ± 2	9.7 ± 1.5*
Matched controls (n = 17)	52 ± 13	1213 ± 120	6.1 ± 2	10.9 ± 1.9
Chronic hypertension (n = 14)	53 ± 11	1307 ± 211	5.5 ± 2	10.3 ± 2.2
Matched controls (n = 14)	52 ± 11	1216 ± 198	5.3 ± 1	10.2 ± 1.7
Smokers				
Preeclamptic toxemia (n = 3)	43 ± 11	1251 ± 83	6.2 ± 1	9.7 ± 1.7
Matched controls (n = 3)	58 ± 7	1306 ± 266	5.5 ± 2	12.1 ± 1.4
Chronic hypertension (n = 9)	63 ± 9	1288 ± 207	5.5 ± 3	11.5 ± 2.8
Matched controls (n = 9)	64 ± 6	1116 ± 142	5.5 ± 2	11.5 ± 2.1

*Significantly different from matched controls, $p < 0.05$.

Patients were classified according to the following criteria. For the diagnosis of preeclamptic toxemia, the patient had to have a blood pressure of 140/90 mm Hg or an increase above baseline of 30 mm Hg in the systolic pressure or 15 mm Hg in the diastolic pressure. Generalized edema and/or proteinuria were used as additional diagnostic criteria. For the diagnosis of chronic hypertension, the patient had to have a blood pressure >140/90 mm Hg detected earlier than 20 weeks of gestation or dating to the prepregnancy period. Patients with diabetes, chronic urinary tract infection, liver diseases, chorioamnionitis, and chronic hypertension with superimposed preeclamptic toxemia were excluded from the study.

An aliquot of 20 ml of venous blood was obtained within an hour of delivery by means of a plastic syringe and stainless steel needle to assess the patient's zinc status. Samples were analyzed for plasma zinc, red blood cell zinc, and heat-labile alkaline phosphatase, a zinc-requiring enzyme. The samples were also analyzed for whole-blood cadmium. The procedures for sample collection and analysis have been reported previously.[5] Smoking status was determined by analysis of plasma thiocyanate, by the clinical record, and by questionnaires. Patients with thiocyanate values <60 μm/L were defined as nonsmokers and those with values >59 μm/L were defined as smokers.

Samples of placental tissue were obtained after several cotyledons had been perfused with 2 L of cold 0.9% saline solution to remove excess blood; the membranes and blood vessels were removed. Each sample was analyzed for placental cadmium and placental zinc.

The patient population was divided into two groups, those parturients with chronic hypertension and parturients with preeclamptic toxemia. The groups were further subdivided into smokers and nonsmokers. Each patient was then matched with a normal control subject based on age, parity, and smoking status.

Data analysis. Statistical analyses were performed with the BMDP statistical software package[10] and a Dec Vax 11/750 computer with a Unix operating system. Data analysis consisted of descriptive statistics, t tests, and simple correlations to obtain an overview of significant differences between the groups (smokers and nonsmokers) and interrelationships between the various biochemical indices. One-way analysis of variance was done to assess significance for a given trace element between the normal parturients, parturients with chronic hypertensive disorder, and pregnancy-induced hypertension. Significance was accepted at $p < 0.05$.

Results

Forty-three hypertensive patients and their matched control subjects were included in the study. Since there were only three parturients with preeclamptic toxemia who smoked, they were not included in the statistical analyses. However, they were included in the tables.

Maternal and placental zinc status, and whole blood and placental cadmium levels are presented in Tables I and II, respectively. The results in Table I suggest that there were no differences in the various zinc indices between chronic hypertensive parturients and normal control subjects in either of the smoking groups. However, in parturients with preeclamptic toxemia, the plasma zinc level was 19% lower than in normal subjects. This was true for nonsmokers and smokers. Patients with preeclamptic toxemia had the lowest plasma zinc level of any group. Neither the red blood cell zinc nor heat-labile alkaline phosphatase levels were different.

Table II. Whole-blood and placental cadmium with regard to type of hypertension and smoking

	Whole-blood cadmium (ng/gm) (mean ± SD)	*Placental cadmium (ng/gm) (mean ± SD)*
Nonsmokers		
Preeclamptic toxemia (n = 17)	0.63 ± 0.3	5.95 ± 2.3
Matched controls (n = 17)	0.60 ± 0.3	5.89 ± 2.3
Chronic hypertension (n = 14)	0.64 ± 0.3	5.66 ± 3.3
Matched controls (n = 14)	0.63 ± 0.3	6.41 ± 2.6
Smokers		
Preeclamptic toxemia (n = 3)	1.98 ± 1.2	10.53 ± 1.5
Matched controls (n = 3)	0.99 ± 0.2	6.86 ± 1.2
Chronic hypertension (n = 9)	1.29 ± 0.4	14.1 ± 8.4
Matched controls (n = 9)	1.22 ± 0.8	11.7 ± 4.0

None of the values were significantly different from matched controls at $p < 0.05$.

There were no significant differences in placental zinc levels between parturients with chronic hypertension and their controls; this was true whether or not they smoked. The level of placental zinc was 12% lower in nonsmoking parturients with preeclamptic toxemia; there was a similar trend in the three smokers with preeclamptic toxemia.

The whole-blood cadmium level, which is shown on Table II, was not different between control patients and those with chronic hypertension or preeclamptic toxemia. When smoking status was taken into account, normal smokers had higher levels of cadmium than normal nonsmokers ($p < 0.01$). Chronic hypertensive patients who smoke also have higher whole blood cadmium levels than chronic hypertensive patients who do not smoke. There were very few parturients with preeclamptic toxemia who smoked. Their cadmium levels were similar to normal and chronic hypertensive smokers.

Placental cadmium levels were not statistically different between normal subjects and hypertensive parturients regardless of the type of hypertensive disorder. However, chronic hypertensive patients who smoked had the highest placental cadmium levels. Smoking significantly increased placental cadmium levels regardless of hypertensive status.

Relationships between levels of maternal whole blood cadmium and the different zinc indices in maternal blood were tested with regression analysis in smokers and nonsmokers. A significant correlation was found between levels of whole blood cadmium and plasma zinc in nonsmoking parturients with preeclamptic toxemia ($r = 0.53$, $p < 0.05$). No correlations with the other zinc indices were found in either normal subjects or chronic hypertensive patients.

Comment

Several studies have been published in the past that suggested a relationship between zinc status and hypertensive disorders during pregnancy.[1-5] Other authors have hypothesized a role for cadmium.[2, 9] The purpose of our study was to comprehensively assess various indices of zinc status and examine potential interactions with cadmium in a carefully diagnosed and matched population. The major findings are that patients with preeclamptic toxemia, but not chronic hypertensive patients, have altered zinc indices and an abnormal relationship between whole blood cadmium and plasma zinc levels. The results support a marginal zinc deficiency in patients with preeclamptic toxemia but not in those with chronic hypertension. The role of cadmium in the cause of preeclamptic toxemia remains unclear.

Until recently, plasma zinc was the only zinc index studied.[1-3] Adeniyi[4] recently reported a relationship between plasma zinc, maternal leukocyte zinc, and preeclamptic toxemia. Compared with normal subjects, pregnant patients who developed preeclamptic toxemia and were delivered of small for gestational age infants had significantly lower levels of maternal leukocyte zinc. No difference was found in patients with preeclamptic toxemia who gave birth to appropriate for gestational age infants. The author did not control for maternal age, parity, or smoking status. Our results also support altered plasma zinc in pregnant patients wtih preeclamptic toxemia. Regardless of smoking status, the level of plasma zinc was 19% lower than in the matched control subjects. Mean maternal plasma zinc levels of 42 μg/dl at term were well below the mean value of 57 μg/dl for plasma zinc previously reported for our population.[5]

In view of the potential role of zinc deficiency in the cause of pregnancy-induced hypertension, the effect of zinc supplementation during pregnancy was studied by Hunt et al.[11] Zinc supplementation reduced the occurrence of pregnancy-induced hypertension in Mexican-American women, but the occurrence of hypertension was not related to serum zinc concentrations.

Placental zinc levels in patients with preeclamptic toxemia were also significantly lower than in matched control subjects. This finding has not been previously reported. In contrast, levels were not different in par-

turients with chronic hypertension. If it is assumed that placental zinc is representative of zinc levels in other organs in the body, then it may be speculated that preeclamptic toxemia is associated with depletion of zinc stores in other body tissues and in the plasma. This supports the hypothesis that suboptimal zinc stores may be the cause of the hypertensive disorder. However, preeclamptic toxemia is primarily a disease of primigravid women, whereas depleted zinc levels are more common in multiparous patients.[7] Nevertheless, there are some clinical and laboratory manifestations common to preeclamptic toxemia and zinc deficiency in laboratory animals.[2] These include abnormal water balance, elevated hematocrit, altered prostaglandin synthesis, bleeding tendency, abnormal platelet aggregation, and growth retardation of the fetus.

Regression analyses were done to determine whether the different zinc indices in blood are influenced by whole-blood cadmium levels. A significant correlation was found between the level of whole-blood cadmium and plasma zinc in nonsmoking parturients with preeclamptic toxemia. This has not been reported previously. No relationships were found in normal parturients or in those with chronic hypertension. Because of these findings, we cannot reject the hypothesis that preeclamptic toxemia results from increased sensitivity to cadmium or to an unexplained cadmium-zinc interaction. However, higher levels of whole-blood or placental cadmium were not found and may not contribute directly to the hypertension disorder.

There are several theories that attempt to explain an association with zinc and cadmium in preeclamptic toxemia. Mukherjee et al.[12] suggested that lowered plasma zinc levels in preeclamptic toxemia are related to the concurrent hypoalbuminemia that occurs in preeclamptic toxemia. Others have suggested that marginal zinc deficiency states associated with pregnancy and a low-protein diet might confer an increased sensitivity to cadmium toxicity.[2] This condition may in turn result in vasoconstriction, sodium retention, altered catecholamine metabolism, increased renin activity, and resultant hypertension. However, if this were true, one would expect an increased incidence of preeclamptic toxemia in smokers who have higher cadmium levels. In contrast, fewer smokers develop preeclamptic toxemia.[13] Our study does not strongly support the cadmium hypothesis because neither whole-blood nor placental cadmium levels differed among normal controls, chronic hypertensive patients, or parturients with preeclamptic toxemia. This was true regardless of smoking status.

There is further support for the role of cadmium in hypertension. It has been suggested that cadmium could influence sodium and calcium metabolism in experimental hypertension.[14] Application of moderate cadmium caused a marked elevation in blood pressure and an increase in sodium retention. Further investigation suggested an increase of intracellular calcium concentrations in rats with cadmium-induced hypertension. The increased intracellular sodium concentrations caused an increase in intracellular calcium concentrations, which in turn induced an increased vascular tone and resulted in an elevation of blood pressure.[14]

We conclude that maternal plasma zinc, placental zinc, and the relationship between whole-blood cadmium and plasma zinc is altered in parturients with preeclamptic toxemia, but not in those with chronic hypertension. Maternal red blood cell zinc and heat-labile alkaline phosphatase are not changed. The results suggest a marginal zinc deficiency in patients with preeclamptic toxemia but not in those with chronic hypertension. The role of cadmium in the cause of preeclamptic toxemia remains unclear.

This study suggests a need for additional well-controlled studies of the relationship between zinc supplementation, tissue and plasma zinc, cadmium levels, and the incidence of preeclamptic toxemia.

Erythrocyte cation metabolism in preeclampsia

James R. Sowers, MD, Michael B. Zemel, PhD, Richard A. Bronsteen, MD, Paula C. Zemel, PhD, Mary F. Walsh, PhD, Paul R. Standley, MS, and Robert J. Sokol, MD
Detroit, Michigan

To determine if there are abnormalities in cellular cation regulation in pregnancy-induced hypertension, erythrocyte intracellular levels of calcium, magnesium, sodium, and potassium and circulating parathyroid hormone and "endoxin" were examined in 13 women with pregnancy-induced hypertension and 34 control subjects matched for gestational age (≥35 weeks). Both endoxin and parathyroid hormone levels were higher in patients with pregnancy-induced hypertension than in control subjects (endoxin, 294 ± 34 vs. 210 ± 19 pg/ml, $p < 0.05$; parathyroid hormone, 0.65 ± 0.05 vs. 0.60 ± 0.03 ng/ml); the increase was significant only for endoxin. Intracellular calcium was higher in the patients with pregnancy-induced hypertension (0.033 ± 0.010 vs. 0.015 ± 0.001 mEq/L, $p < 0.05$, in the patients with pregnancy-induced hypertension and control patients, respectively) but intracellular sodium, potassium, and magnesium levels were not different. This intracellular calcium elevation may be caused directly by the increase in parathyroid hormone or indirectly by the observed elevation in endoxin. Our data indicate that the observed effect is specific because no changes in intracellular sodium, potassium, or magnesium levels were found. (AM J OBSTET GYNECOL 1989;161:441-5.)

Key words: Preeclampsia, cation metabolism, calcium, endoxin

Studies of the cause and pathogenesis of pregnancy-induced hypertension (PIH) and preeclampsia have reported primary abnormalities related to immunologic, hemodynamic, dietary, endocrine, and uteroplacental blood flow function.[1] However, cellular abnormalities in PIH remain poorly understood. Recently some attention has been directed to the possibility that altered cellular cation metabolism may play a role in the pathogenesis of PIH and preeclampsia.[2-6]

Hypertension is more common in blacks than in whites. Although the mechanisms for these racial differences are not clear, there is accumulating evidence to indicate that differences in cellular cation metabolism may partially be responsible for the racial differences in hypertension.[7] Cooper et al.[7] recently reported that untreated black patients with hypertension have elevations in both erythrocyte sodium and platelet ionized calcium levels. It has been suggested that concomitance of elevated cellular sodium and calcium may result from the elaboration of a natriuretic substance, "endoxin," that inhibits sodium-potassium adenosine triphosphatase activity and thereby elevates intracellular sodium levels.[8] Accordingly, elevations in sodium would then result in decreased sodium-calcium exchange and elevations in cellular calcium.[8] Another possible mechanism for elevated intracellular calcium is suggested by recent observations regarding parathyroid hormone, a known calcium ionophore, in several tissues, including vascular smooth muscle.[9] Our investigative group has recently reported that increasing dietary salt in black patients with hypertension results in significant increases in levels of both parathyroid hormone and intracellular calcium.[10] We have recently found that parathyroid hormone inhibits erythrocyte sodium-potassium adenosine triphosphatase activity (unpublished data). These data suggest that parathyroid hormone may raise levels of intracellular calcium both directly, as a calcium ionophore, and/or indirectly, by inhibiting sodium-potassium adenosine triphosphatase activity, thus reducing sodium-calcium exchange.

This study was undertaken to evaluate erythrocyte cation concentrations and those circulating factors that may regulate intracellular cations in black patients with preeclampsia and normotensive control subjects of similar gestational age.

Material and methods

We evaluated 47 primigravid black women with gestational age ≥35 weeks. Patients with preexisting intrinsic renal disease, diabetes mellitus, or hypertension were excluded from the study. Preeclampsia was defined by standard American College of Obstetricians and Gynecologists criteria for hypertension and proteinuria. Specifically, hypertension was defined as the presence of a blood pressure of 140/90 mm Hg. Proteinuria was defined as excretion of >300 mg of urinary protein/24 hours. None of the patients studied took antihypertensive medication at the time of study. Table

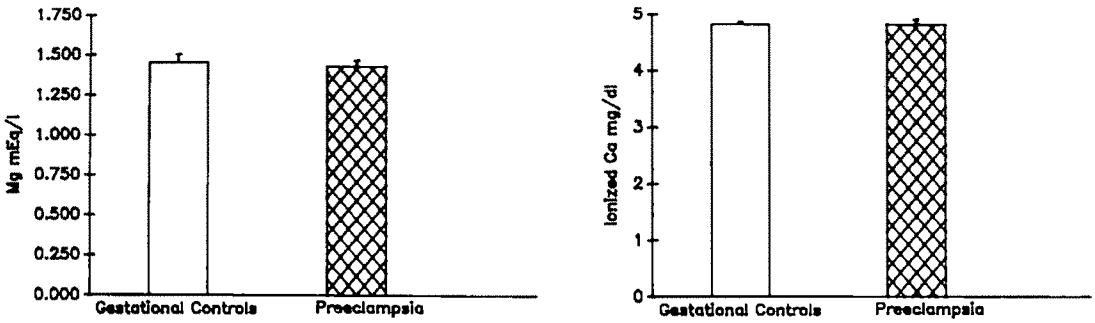

Fig. 1. Serum magnesium and ionized calcium in patients with preeclampsia and normotensive gestational control subjects (mean ± SE).

Table I. Demographic characteristics of study populations

Group	*N*	*Age (yr)*	*Mean gestational age (wk)*	*Mean arterial pressure (mm Hg)*
Control subjects	34	25.2 ± 2.2	38.0 ± 0.5	79.2 ± 1.8
Women with preeclampsia	13	23.7 ± 1.1	38.7 ± 0.6	98.5 ± 3.5*

All data expressed as mean ± SEM.
*$p < 0.001$ versus control subjects.

I describes the key characteristics of the two study groups. Informed consent was received from all patients. This study was approved by our institutional review board.

Blood samples were obtained by venipuncture with the patients in the lateral decubitus position. The ionized calcium level was measured by a calcium-specific electrode standardized to pH 7.40 (model I CAI, Radiometer, Copenhagen, Denmark) in serum obtained under anaerobic conditions and analyzed in duplicate either immediately or in serum frozen up to 24 hours. Serum sodium, potassium, and magnesium levels were measured by atomic absorption spectrophotometry. Heparinized blood for determination of erythrocyte intracellular cation levels was collected in prechilled tubes and prepared as follows. The sample was centrifuged at 1500 *g* for 10 minutes at 4° C, and the plasma and buffy coat were removed by aspiration. The remaining erythrocytes were then washed three times in ice-cold 140 mmol/L choline chloride with 10-minute centrifugations at 1500 *g* and 4° C between washings. After the last washing, the hematocrit and cell count for each sample preparation were determined and aliquots were prepared for determination of cation levels by lysing in one volume of distilled-deionized water. Samples were frozen for subsequent analysis.

Sodium and potassium levels were determined in the aliquots prepared for intracellular cation analysis by flame atomic absorption after dilution in the appropriate diluent to suppress ionization interference (26 mmol/L potassium chloride for sodium determination and 43.5 mmol/L sodium chloride for potassium determination). Erythrocyte calcium and magnesium levels were determined by atomic absorption after dilution of the washed sample in 0.5% lanthanum chloride and 0.001% Triton X-100.

Serum levels of parathyroid hormone were measured by a radioimmunoassay that uses an antibody directed to the midportion of the human parathyroid molecule.[10] Endoxin was assayed by a radioimmunoassay procedure with a Rainin digoxin antibody. All data were evaluated for normality of distribution and equality of variance before determination of differences between sample means by *t* test. All data are expressed as mean ± SEM.

Results

Mean age and gestational age were not different for the patients with preeclampsia and the control groups (Table I). Mean arterial blood pressure was obviously greater in the preeclamptic group. The young black women were all from similar socioeconomic backgrounds and resided in urban Detroit.

Fig. 1 shows that the serum magnesium and plasma ionized calcium levels in the two groups were comparable. Similarly, intracellular levels of sodium, potassium, and magnesium in erythrocyte were not different in the two groups (Fig. 2). However, intracellular calcium levels were twice as high ($p < 0.01$) in the erythrocytes from patients with preeclampsia (0.033 ± 0.010 mEq/L) as in the normotensive control patients (0.015 ± 0.001 mEq/L) (Fig. 2).

Fig. 3 indicates that plasma levels of endoxin were greater ($p < 0.05$) in the patients with preeclampsia

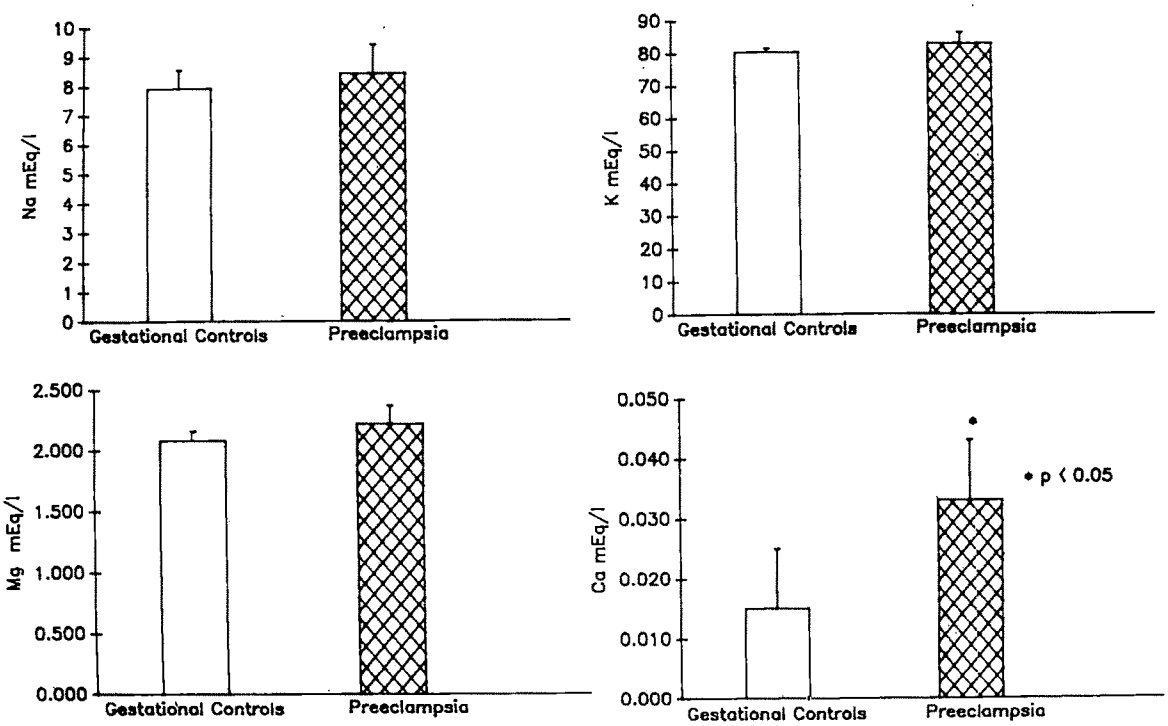

Fig. 2. Erythrocyte cation levels in patients with preeclampsia and gestational control subjects (mean ± SE).

(294 ± 34 pg/ml) than in the gestational control subjects (210 ± 19 pg/ml). Serum parathyroid hormone levels were higher in the patients with preeclampsia (0.65 ± 0.05 ng/ml) than in the normotensive gestational control subjects (0.60 ± 0.03 ng/ml), but this difference only approached statistical significance ($p < 0.1$, Fig. 4).

Comment

This study demonstrates that erythrocyte calcium levels are clearly elevated in young black patients with preeclampsia when compared with normotensive gestational control subjects. This increase was specific for calcium because intracellular concentrations of sodium, potassium, and magnesium were not different for the two study groups. This increase in erythrocyte calcium also appears to be independent of serum ionized calcium levels, which were not altered in the group of patients with preeclampsia.

The increase in erythrocyte calcium levels is similar to the twofold elevation in platelet calcium in preeclampsia that was recently reported.[11] Increased calcium concentrations also have been observed in placental tissue from patients with preeclampsia.[12] If these observations in erythrocyte, platelet, and placental tissue extend to maternal vascular smooth muscle, then increased cellular calcium may be causally related to the enhanced vascular reactivity observed in preeclampsia.[13] Increased vascular constriction related to elevated smooth muscle calcium levels may be a factor in the increased incidence of uteroplacental hypoperfusion seen in preeclampsia. Nitrendipine, a calcium channel blocker, has been shown to markedly inhibit vasoconstrictor responses in human chorionic arteries.[14]

Increased intracellular calcium has been reported in erythrocytes[10] and in platelets[7] of patients with essential hypertension. This increase has been attributed both to intrinsic cellular defects and alterations in circulating factors (e.g., natriuretic factor (endoxin) and parathyroid hormone), which may then directly or indirectly affect increases in intracellular calcium. In our study, levels of endoxin, a digoxin-like inhibitor of sodium-potassium adenosine triphosphatase, were higher in women with preeclampsia than in normotensive gestational control subjects. This factor may increase peripheral vascular resistance through inhibition of sodium-potassium adenosine triphosphatase activity.[8] However, if this were an important operative mechanism for increased cellular calcium levels, then intracellular sodium levels should also be elevated.[8] In this study erythrocyte sodium levels were slightly (not significantly) higher in patients with preeclampsia than in gestational subjects. This observation is in agreement with previous reports that erythrocyte sodium levels are not elevated in PIH[4] or in preeclampsia.[5] Although short-term exposure of erythrocytes to digoxin results in a decrease in sodium-potassium adenosine triphos-

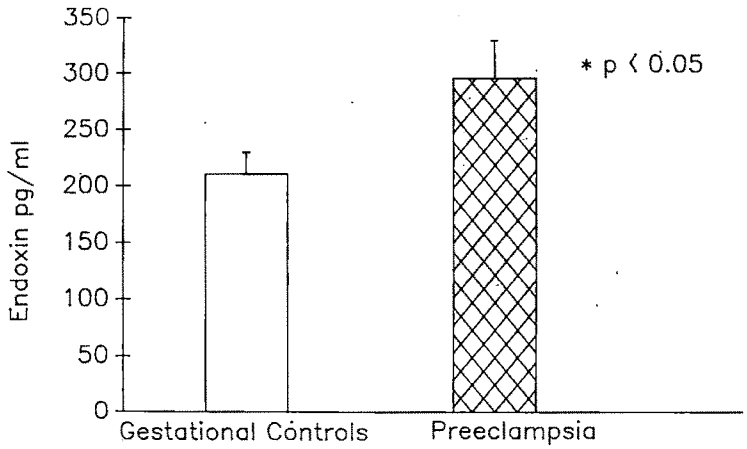

Fig. 3. Plasma endoxin levels in patients with preeclampsia and gestational control subjects (mean ± SE).

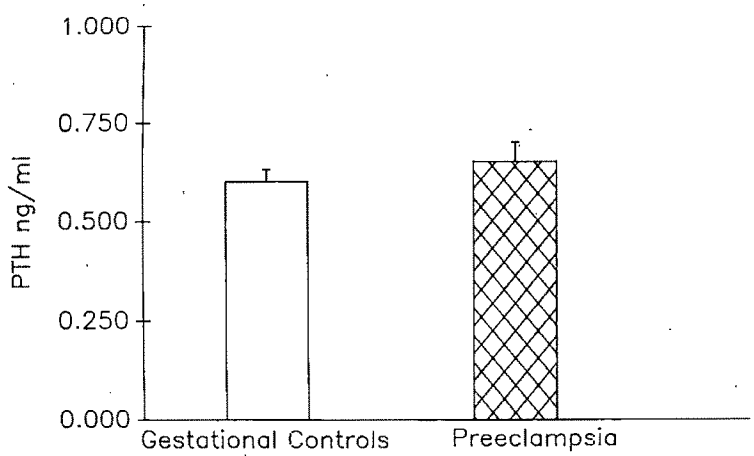

Fig. 4. Serum parathyroid hormone *(PTH)* levels in patients with preeclampsia and gestational control subjects (mean ± SE).

phatase activity and an accompanying increase in cell sodium,[15] long-term exposure is associated with compensatory increases in sodium-potassium adenosine triphosphatase activity and a return to pretreatment cell sodium levels.[15] Accordingly, these observations may explain the minimal increases in erythrocyte sodium levels despite significant elevations in endoxin in preeclampsia.

In this study circulating parathyroid hormone levels were elevated and approached statistical significance in patients with preeclampsia despite the fact that serum concentrations of ionized calcium and magnesium were not different in the two study groups. Our observation of similar calcium levels in patients with preeclampsia and controls is in agreement with previous observations by Richards et al.[16] Normal ionized calcium levels with a tendency toward increased parathyroid hormone levels could reflect decreased calcium intake and/or absorption, or increased urinary excretion of calcium. Regardless of the cause, elevated parathyroid hormone levels may be an important factor with regard to elevated erythrocyte calcium levels. Indeed, parathyroid hormone is a well-defined calcium ionophore in a variety of cell types, including erythrocytes and vascular smooth muscle.[9] Recent data from our laboratory suggest that parathyroid hormone elevations in salt-sensitive hypertensive black patients may be causally related to salt-induced elevations in blood pressure,[10] possibly through the action of parathyroid hormone as a calcium ionophore.[9]

Thus, to the extent that data from erythrocytes may be extrapolated to vascular smooth muscle, our data suggest a potential role for parathyroid hormone in increased cellular uptake of calcium in vascular smooth muscle, thereby increasing vascular reactivity in preeclampsia.

Immunoregulatory activity in supernatants from cultures of normal human trophoblast cells of the first trimester

Mrinal K. Sanyal, PhD,[a] Charles J. Brami, MD, Paul Bischof, PhD,[b] Edwina Simmons, MD, Eytan R. Barnea, MD, John M. Dwyer, MD, PhD, and Frederick Naftolin, MD, DPhil
New Haven, Connecticut, and Geneva, Switzerland

Supernatants from isolated trophoblast cell cultures (trophoblastic fluid) derived from first-trimester human placentas were assessed for immunoregulatory activity. Trophoblastic fluid at different days of culture consistently inhibited the blast transformation of allogenic lymphocytes. This suppressor effect had no apparent correlation with biosynthesis of human chorionic gonadotropin by trophoblast cells, since this hormone was secreted into the culture fluid only for the initial 3 days. However, the culture fluids of such purified trophoblast cells contained an immunosuppressive factor, pregnancy-associated plasma protein A, which was measurable throughout the culture period of 8 days. The presence of pregnancy-associated plasma protein A in significant amounts in trophoblastic fluid collected at daily intervals indicated a continuous secretion ability of pregnancy-associated plasma protein A by trophoblast cells in culture parallel to the suppressive immunoregulatory effect of the fluid. Such immunosuppressive effect was absent in the culture fluids of control BeWo malignant trophoblast cells; the BeWo cell culture fluids had markedly reduced levels of pregnancy-associated plasma protein A. The culture supernatant of normal trophoblast cells of placentas from first-trimester pregnancy activated in vitro the generation of a population of suppressor lymphocytes. This effect is generally considered responsible for immunologic tolerance. Therefore demonstration of immunosuppressive effects and the presence of relatively high levels of pregnancy-associated plasma protein A in trophoblastic fluid indicate that such proteins secreted by the trophoblast cells may be important in the local immunoregulatory processes of the fetal allograft. (Am J Obstet Gynecol 1989;161:446-53.)

Key words: Pregnancy-associated plasma protein A, first trimester, immunosuppression, suppressor cell activation, trophoblast cell culture

As an intervening layer of cells between fetal and maternal tissue, the placental trophoblast is likely to play a crucial role in the regulation of maternal immune responses to the fetus (allograft) during pregnancy. The absence of expression of major histocompatibility complex antigens on the syncytiotrophoblast, the ability of the fetal placenta to form complexes with maternal-blocking antibodies, the existence of strong suppressor cell activity in the fetus, and the production of molecules by the trophoblast or maternal decidua that induce immunosuppression in the microenvironment of the placenta are among the suggested mechanisms of immunoregulation that are of considerable current interest.[1, 2]

In this regard, Bischof et al.[3, 4] and Barnea et al.[5] have shown that human decidua and trophoblast cells produce specific proteins, such as pregnancy-associated plasma protein A, which have the capability to inhibit in vitro lymphoblast transformation. It has also been reported that placental steroid and protein hormones could regulate the local immune responses.[6] In addition, immunoglobulins eluted from murine placentas specifically enhanced the tumor allografts of paternal strain placed on a maternal recipient. IgG fractions isolated from human placental eluates prevented the production of a macrophage-inhibiting factor by maternal lymphocytes responding to paternal antigens.[7] Thus it is likely that the microenvironment of the trophoblast interface is an important element in the main-

tenance of the fetal allograft. The factor produced by the trophoblast cells may be involved in the regulation of this process during gestation.

Therefore in the present study we examined the immunosuppressive activity on mononuclear cells and also the suppressor T cell activation capability of culture supernatants of isolated and purified first-trimester human placental trophoblast cells (trophoblastic fluid). In addition, we simultaneously assayed concentrations of human chorionic gonadotropin (β-hCG) and pregnancy-associated plasma protein A in the same trophoblast cell culture supernatant to determine whether trophoblastic cells may produce immunoregulatory factors that may be important for the maintenance of the fetal allograft.

Material and methods

Trophoblast cell culture. Human trophoblast cells of first-trimester pregnancies were isolated and cultured as primary monolayer cultures by the procedures previously described.[8, 9] In this procedure first-trimester (8 to 12 weeks' gestation), normal human placentas of elective termination of pregnancy by suction procedure were washed in ice-cold normal saline solution, and placental villi were dissected under a binocular microscope (magnification ×50). These villus tissues were then exposed for 10 to 20 minutes to a solution of tissue culture medium 199 (Gibco Laboratories, Grand Island, N.Y.) containing 0.2% trypsin, 0.02% ethylenediaminetetraacetic acid, and 2200 Kunitz units/ml of bovine pancreatic deoxyribonuclease (all from Sigma Chemical Co., St. Louis, Mo.). After constant agitation for 10 minutes, dislodged trophoblast cells were collected by centrifugation at 400 × *g* for 10 minutes. They were then purified by centrifugation through a Ficoll-Hypaque gradient and assessed for viability by the trypan blue exclusion test. Aliquots of trophoblast cells (0.5×10^6 cells/ml) were placed into 35 mm diameter Petri dishes containing tissue culture medium (Waymouth's MB 752/1 and Gey's basal salt solution, 55:45), 15% bovine fetal serum, and antibiotics (penicillin and streptomycin, 100 μg/ml). They were then cultured for various intervals ranging from 1 to 12 days at 37° C in 5% CO_2 and air. The culture medium for these trophoblast cells was changed daily.

BeWo malignant trophoblast cells (gift of Dr. Roland Pattillo, Department of Obstetrics and Gynecology, University of Wisconsin, Milwaukee, Wis.) were used as controls in the present study. These cells were dispersed with a solution of Ca^{2+}- and Mg^{2+}-free Earl's basal salt solution containing 0.05% trypsin and 0.02% ethylenediaminetetraacetic acid. They were then cultured with Waymouth's medium (MB 752/1) that was mixed with Gey's balanced salt solution and bovine fetal serum (50:40:10) in an atmosphere of 5% CO_2 and air at 37° C. The culture medium for BeWo cells was changed daily or at 2- to 4-day intervals.

The supernatants of normal trophoblast cell culture (trophoblastic fluid) or those of BeWo cell culture after centrifugation were frozen at −20° C until used for β-hCG and pregnancy-associated plasma protein A radioimmunoassays (RIA) and in vitro immunosuppressive activity assessment by lymphocytes. The fragments of normal villus trophoblasts adjacent to those used for disaggregation were frozen in liquid nitrogen. These frozen villi were sectioned in a cryostat (4 to 6 μm sections) and used for immunohistochemical studies. For histologic controls, paraffin sections of placental villi and cultured normal trophoblast cells or BeWo malignant cells attached to the chamber slides were stained with hematoxylin and eosin.

Biosynthesis of hCG by trophoblast cells. Biosynthesis of hCG by isolated trophoblast cells was ascertained by immunohistochemical tests and RIA measurement of trophoblast cell homogenates and culture fluids. Immunohistochemical studies were performed with rabbit anti-hCG serum (Cappel, Inc., Malvern, Pa.) to identify hCG-bearing cells.[8] All preparations were examined by indirect immunofluorescence binding with diluted antisera (1:100). The incubation period for diluted antisera with tissues and cells was for 4 to 8 hours at 4° C, which was previously found to be optimal. Conjugates of fluorescein isothiocyanate– or tetraethylrhodamine isothiocyanate–labeled sheep antirabbit IgG were used as a second antibody for localization of hCG. The concentration of β-hCG in the trophoblast cell homogenates (10^6 cells/ml in fresh medium) and the trophoblast culture supernatant was estimated by RIA methods with highly specific antisera to β-hCG.

Secretion of pregnancy-associated plasma protein A by trophoblast cells. Pregnancy-associated plasma protein A in homogenized cultured trophoblast cells and culture fluids was measured by an RIA procedure previously described.[10] The antisera used for RIA was produced in the rabbit against a purified preparation of pregnancy-associated plasma protein A. This antiserum was highly specific and had no apparent cross-reactivity with other similar serum proteins.

Responsiveness of human mononuclear cells. Mononuclear cells were isolated from blood donated by healthy adult volunteers by means of standardized techniques. They were recovered by ficoll-Hypaque gradient centrifugation and resuspended in tissue culture media (RPMI 1640) containing 15% bovine fetal serum and antibiotics. For mitogen stimulation of lymphocytes, phytohemagglutinin (Sigma Chemical Co., St. Louis, Mo.) was added to cells suspended at a concentration of 2×10^6 cells/ml. The three phytohemagglutinin doses were chosen in this study to provide the mitogenic stimulation for normal lymphocytes. The fi-

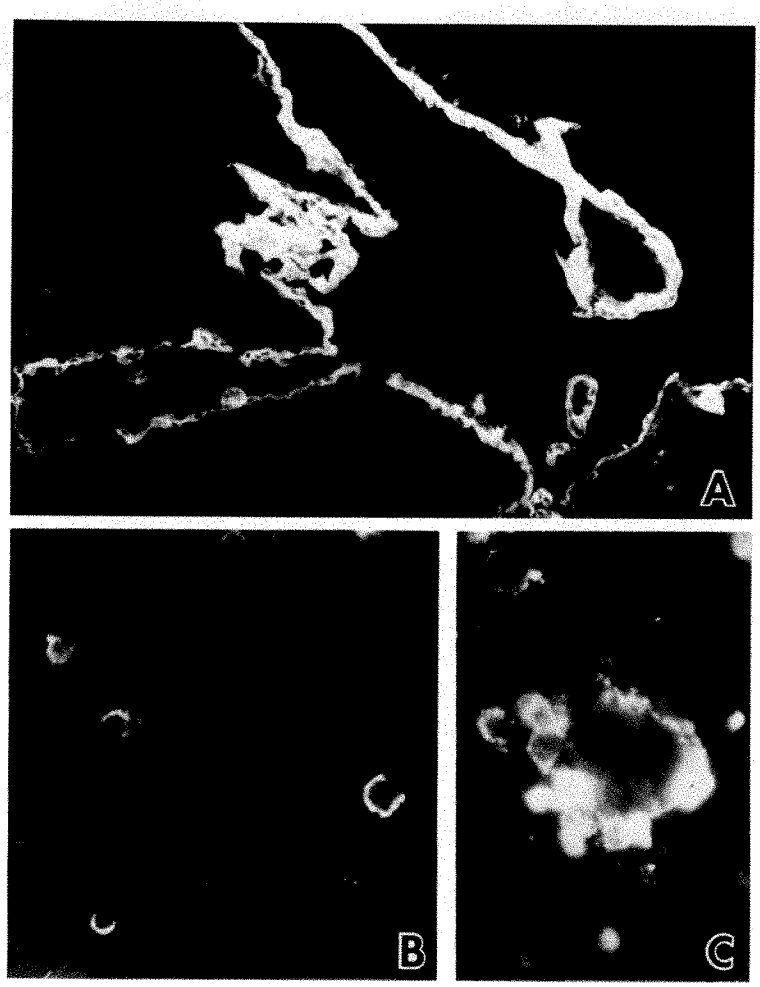

Fig. 1. A, Frozen section of placental villi stained for immunofluorescence localization of hCG by conjugates of anti-hCG and tetraethylrhodamine isothiocyanate. Intense positive staining for hCG could be seen on the outer villus syncytiotrophoblast layer. (×250.) **B,** Dislodged and purified polygonal trophoblast cells treated with conjugates of anti-hCG and tetraethylrhodamine isothiocyanate showed fluorescence staining, indicating presence of hCG in such cells. (×450.) **C,** Multinucleated trophoblast derived cell(s) also stained with anti-hCG and tetraethylrhodamine isothiocyanate conjugate showed localization of hCG. (×450.)

nal concentrations of these three phytohemagglutinin doses in the culture wells were 5 μg/ml (high), 1 μg/ml (medium), and 0.25 μg/ml (low). The culture supernatant from normal trophoblast cell culture (trophoblastic fluid) or that from BeWo cells (25 μl/well) or the same volume of culture medium as a control was added at the initiation of the mitogen stimulation.

After 3 days of culture under standard conditions, 0.5 μCi (tritiated methyl)-thymidine (New England Nuclear, Inc., Boston, Mass., SA 79 Ci/mmol/L) was added to each culture well. One day later the cultured cells were harvested and prepared for tritiated thymidine incorporation assays by means of a liquid scintillation counter. Background counts per minute (cpm) from control cultures without phytohemagglutinin were subtracted from those of phytohemagglutinin-stimulated cultures. The mean counts per minute and standard error of the mean (SEM) from triplicate values of each well were calculated. The suppression of thymidine incorporation into mononuclear cells is expressed as the percentage reduction in the response of phytohemagglutinin, which was calculated with the following formula[11]:

$$\% \text{ Suppression} = 1 - \frac{(\text{cpm responders} + \text{trophoblastic fluid}) \times 100}{(\text{cpm responders} + \text{culture medium})}$$

Generation of suppressor cell activity. To determine whether trophoblastic fluid could produce suppressor T cell activity for immunoregulation, lymphocytes treated with supernatant from normal trophoblast cell cultures were examined for their ability to reduce the

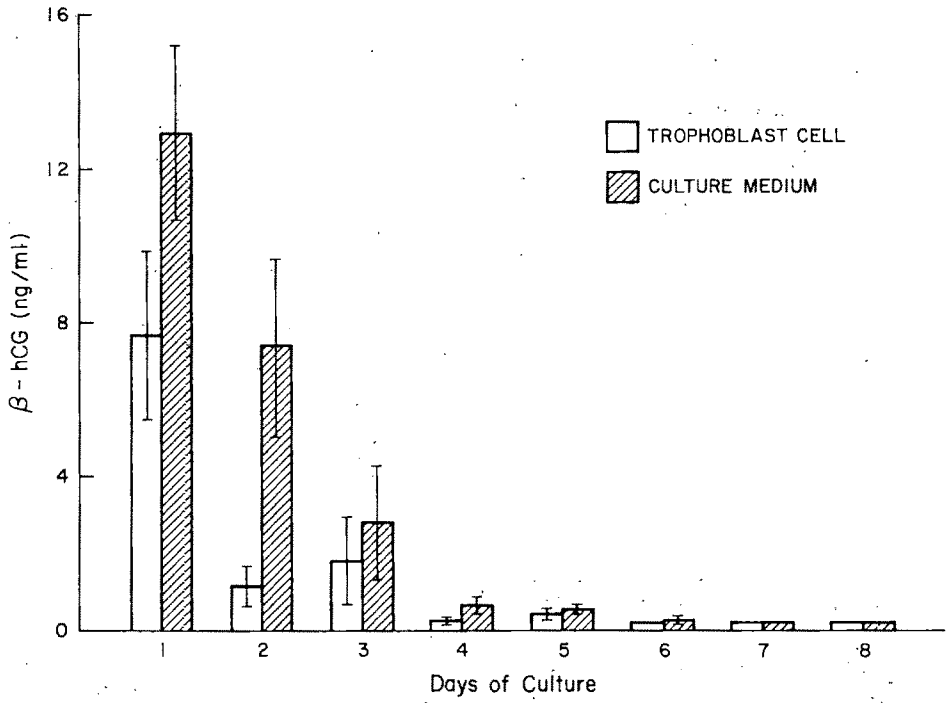

Fig. 2. Concentrations of β-hCG in cells and supernatants of trophoblast cell cultures collected at 24-hour intervals after change of medium. Approximately 10^6 cells/ml were homogenized with culture medium for assessment of β-hCG concentration in cells. Concentrations of this hormone declined steadily with prolongation of culture periods. Hormone concentration in trophoblastic fluid was reduced to a level undetectable by RIA procedures after 3 days of culture.

mitogenic response of mononuclear cells to phytohemagglutinin.[11] Lymphocytes (10×10^6/ml) were cultured with or without supernatants from normal trophoblast cell cultures. The culture volume consisted of 3 ml of suspended lymphocytes for every 1 ml of trophoblastic fluid. After 72 hours, these cells were removed, resuspended in fresh medium, and incubated with mitomycin (Sigma Chemical Co.) at 100 μg/ml concentration for 30 minutes at 37° C. These treated cells were washed four times with buffered salt solution and then assessed for viability by the eosin exclusion procedure. Approximately 85% of mitomycin-treated cells were viable, and these cells were then cocultured with responder mononuclear cells for suppressor cell assays. These assays were performed in microculture plates with wells containing a total of 10^5 normal fresh responder mononuclear cells and an equal number of mitomycin-treated control cells or mitomycin- and trophoblastic fluid–treated lymphocytes. After 72 hours of exposure to phytohemagglutinin (1 μg/ml), cell cultures were exposed to a pulse of tritiated thymidine and terminated as described earlier. Suppression was expressed as the percentage reduction in response to phytohemagglutinin as calculated by the following formula:

$$\% \text{ Suppression} = 1 - \frac{(\text{cpm responders} + \text{TF stimulated cells}) \times 100}{(\text{cpm responders} + \text{control cells})}$$

Results

Characterization of trophoblastic cells and secretion of pregnancy-associated plasma protein A in culture. As described in previous studies, three cell types were recognizable in the cultures of isolated normal trophoblast cells of first-trimester human placentas.[8,9] The most abundant cell type was a medium-sized round or polygonal epithelioid cell with a large nucleus. The second category consisted of larger cells containing many nuclei. The fibroblast cells were greatly reduced in number initially, but prolongation of the culture period tends to increase the population of such cells. The rabbit anti-hCG and tetraethylrhodamine isothiocyanate (or fluorescein isothiocyanate) conjugates clearly stained the intact villus trophoblastic layer of cells (Fig. 1, *A*) and the epithelioid and multinucleated cells during the first 3 days of culture (Fig. 1, *B* and *C*). The BeWo cells also exhibited similar immunostaining with anti-hCG and fluorescein isothiocyanate conjugates.

The levels of β-hCG in cultured normal trophoblast cell homogenates and in trophoblastic fluids during dif-

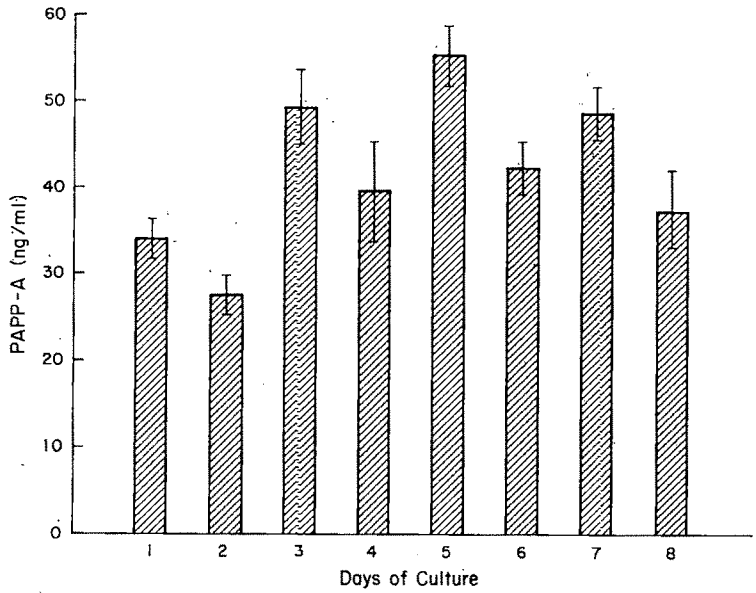

Fig. 3. Pregnancy-associated plasma protein A *(PAPP-A)* concentrations in supernatants of the same trophoblast cell cultures shown in Fig. 2. Undiminished concentration of pregnancy-associated plasma protein A during different days of cultures (24-hour intervals) indicates secretion capability by isolated trophoblast cells of such proteins during culture for prolonged periods.

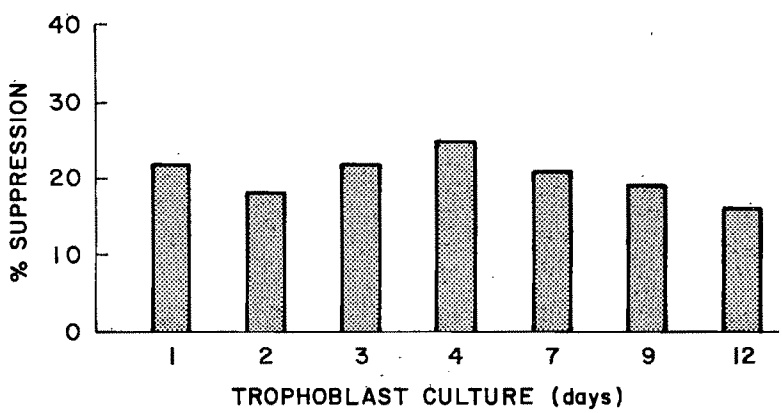

Fig. 4. Immunosuppressive activity of supernatants of trophoblast cell cultures at different days of culture. Immunosuppressive activity in 24-hour culture supernatants after change of medium is approximately 14% to 20% in all culture samples tested. This shows that immunosuppressive activity and pregnancy-associated plasma protein A values in trophoblast cell culture fluid show similar curves and persist during extended cultures as long as 12 days.

ferent days of culture measured by RIA are shown in Fig. 2. The secretion and biosynthetic ability of hCG progressively declined in such cells during culture, as shown by reduced levels of the hormone in trophoblastic fluid, especially after 3 days of culture. However, the increase in pregnancy-associated plasma protein A concentration in trophoblastic fluids, estimated at 24-hour intervals, was unchanged, showing undiminished secretion ability of the protein by such cells in culture for a prolonged period of 8 days (Fig. 3). The pattern of continuous pregnancy-associated plasma protein A secretion contrasted with the decline in hCG levels in the trophoblastic fluid during an extended period of culture.

The BeWo cell culture fluid with a cell population similar to that of normal trophoblast cells produced significant quantities of hCG continuously. However, the levels of pregnancy-associated plasma protein A were reduced in the BeWo cell culture fluids, and at confluency cultures pregnancy-associated plasma protein A concentrations were consistently <14 ng/ml in replicate cultures. The levels of pregnancy-associated

plasma protein A in the initial culture medium containing bovine fetal serum were low (<5 ng/ml).

Effects of trophoblastic culture fluids on allogenic lymphocytes. Immunosuppression studies with trophoblastic culture fluids and lymphocytes were performed using the following three experimental protocols: (1) supernatant samples of trophoblast cell cultured for 3 to 5 days from different placentas were combined and used for blast-transformation of one population of allogenic lymphocytes; (2) the effects of combined trophoblastic fluid from one placental trophoblast cell culture on lymphocytes from different subjects were assessed; and (3) immunosuppressive effects were measured in trophoblastic fluid collected on different days of culture, at 24-hour intervals in cultures for prolonged periods.

In the first series, trophoblastic fluid from nine different placentas were used for blast-transformation of one population of allogenic lymphocytes. Trophoblastic fluid from all nine placental tissues significantly inhibited blast-transformation. The mean counts per minute ± SEM for all control responder cells was 25,672 ± 992, whereas for trophoblastic fluid collected on the same days of culture, the overall response of the same cells was 21,337 ± 763. This represented a significant reduction in tritiated thymidine incorporation into allogenic lymphocytes after trophoblastic fluid treatment (16.1% ± 3.0% suppression, $p < 0.01$, t test). In the second series of experiments, the effects of combined trophoblastic fluid from each placental culture of 3 to 5 days assayed on different populations of phytohemagglutinin-stimulated lymphocytes isolated from eight different subjects are illustrated in Table I. Control cultures gave an average value of 30,056 ± 2258 cpm (mean ± SEM), and this was significantly reduced to 25,646 ± 1921 cpm by trophoblastic fluid ($p < 0.01$, paired t test), which represented an average of 15.0% ± 1.7% suppression. Finally, experiments that used samples of trophoblast cells and fluid at different periods of culture also showed that the immunosuppressive effects of the supernatants of primary trophoblast cultures evaluated by the same methods persisted throughout the culture period tested (days 1 to 12) at a level between 15% and 20% as shown in Fig. 4.

†Responder lymphocyte cells from six of 11 subjects studied with positive suppression.

In contrast to normal trophoblast cells of the first trimester, the BeWo malignant cell culture fluid did not show immunosuppression under identical experimental conditions (Table II). Responder lymphocytes from six different subjects were used, and no significant immunosuppression was demonstrated by tritiated thymidine incorporation procedures.

Induction of suppressor cell activity by trophoblastic fluid. In this study responder lymphocytes were collected from 11 different subjects at random. Preincubation of mononuclear cells with trophoblastic fluid from normal trophoblast culture enhanced suppressor activity in six of 11 subjects (Table III). Cells from the remaining five subjects in our study group were non-

responsive; lymphocytes exposed to the same trophoblastic fluid did not reduce the mitogen-induced transformation of allogenic responder cells. The degree of suppression in the six subjects also was variable and ranged from 8% to 61%. In cells from three of six subjects, more than 50% suppression could be achieved under the conditions used in our assay system. The overall average suppression in these six subjects was 38.33% ± 8.24%, and the mean ± SEM of tritiated thymidine incorporation of controls (15,060 ± 701 cpm) and treated subjects (9199 ± 1059 cpm) were significantly different in the paired t test ($p < 0.01$).

Comment

The effects of various pregnancy-related serum proteins and hormones on maternal immune response have been previously studied. Results have shown that they may play an important role in immunoregulatory processes during pregnancy. The specific factors involved and the mechanisms of immunoregulation at the cellular levels are still unclear. The suggestion that placental peptide factors, especially pregnancy-associated serum protein A, may significantly contribute in immunoregulation has been a compelling possibility.[3,4] The present study demonstrated the possible immunoregulation capabilities of trophoblast cells of the human first-trimester pregnancy by such factors. Isolated trophoblast cells from this period of pregnancy secreted pregnancy-associated plasma protein A in culture, and the same culture fluid has been found to be highly immunosuppressive. In addition, this study also showed that trophoblast cell-culture fluid could generate suppressor cells,which indicates the possibility of participation of trophoblast cells in local immunoregulation at the interface between fetal and maternal compartments in such processes.

In cultures of isolated trophoblast cells of the first trimester the polygonal epithelioid cells were presumably cytotrophoblasts, and the multinucleated cells were formed by aggregation of the trophoblast cells resembling syncytiotrophoblast cells. The trophoblastic origin of these cells in the present study has been ascertained by their morphology and hCG biosynthesis capability (Figs. 1 and 2). These cells also secreted substances in the culture fluid that consistently reduced the responsiveness of lymphocytes to phytohemagglutinin. This in vitro suppressor effect of trophoblastic fluid was observed in all the monolayer cultures, even for prolonged cultures for 12 days, when hCG hormone biosynthesis had ceased (Fig. 4). Since several trophoblast cell types were present in normal first-trimester trophoblastic cultures; which cell types were responsible for immunoregulatory effects remain uncertain.

The immunosuppressive effect was unrelated to hCG secretion capability, since both the cell types of our study; normal trophoblast cells and BeWo malignant cells synthesized this hormone (Fig. 2). The culture fluids of BeWo cells had no detectable immunosuppressive effect, and their pregnancy-associated plasma protein A levels were relatively low (Table II). In contrast, the immunosuppressive effect of trophoblastic fluid from normal trophoblast cells correlated with the pregnancy-associated plasma protein A secretion capability throughout the culture period (Figs. 3 and 4). Since pure pregnancy-associated plasma protein A preparations have also been shown to be immunosuppressive by the same allogenic lymphocyte tests,[3] it is therefore likely that pregnancy-associated plasma protein A in trophoblastic fluid may have contributed in part to the immunosuppressive effects of trophoblastic fluid. The data of the present study showing that the trophoblastic fluids consistently reduced phytohemagglutinin-stimulated proliferative response of lymphocyte samples support this suggestion. Trophoblastic fluid produced a 15% to 20% reduction in tritiated thymidine incorporation into phytohemagglutinin-stimulated lymphocytes, indicating significant overall immunosuppressive capabilities of trophoblastic fluid in all the samples tested (Table I). In these immunosuppression studies, both the suppressor and effector cells were from one patient and had identical human lymphocyte antigen (HLA) haplotypes.

In our subsequent studies of the ability of trophoblastic fluid to activate suppressor cell activity, the indicator cultures contain responder lymphocytes that were randomly selected and may have expressed human lymphocyte antigen haplotypes that were different from those of the suppressor cells (Table III). In this study the reduced responsiveness of lymphocytes to phytohemagglutinin in the presence of the trophoblastic fluid–treated cells was recorded in six of 11 subjects. This response measures suppressor cell activity that exceeds the normal spontaneous suppressor cell activity of the control cultures; no suppressor cell activity was generated by 3 days of allogenic coculture in these indicator systems.[11] It is possible that the variable degree of genetic differences between the human lymphocyte antigen haplotypes was responsible for the negative results in five study subjects. Nevertheless, the possibility of suppressor T-lymphocyte activation by secretory products derived from first-trimester trophoblast cells was clear from these data.

It is now established that major histocompatibility complex class 1 antigens (HLA-A, HLA-B, and HLA-C) are not expressed in the human syncytiotrophoblast cells but messenger ribonucleic acid for them could be expressed.[12,13] HLA-DR antigen was also not expressed normally in trophoblastic tissues, but under specific culture conditions or transformed neoplastic condition,

they may be expressed in such tissues.[8, 14] HLA-DR antigen is responsible for activation of T-lymphocytes,[15] and this process may be highly significant during early gestation when syncytiotrophoblasts were absent or reduced over the cytotrophoblast cell layer. The trophoblast and decidual cells produce immunoregulatory molecules that may generate suppressor cells to help embryo implantation and prevent rejection of the conceptus.[16] Presumably pregnancy-associated plasma protein A is one such factor produced by human trophoblast and decidual cells,[4] and combined effects of such factors were responsible for the suppressor effects of the trophoblast cells.

Thus it seems likely that human trophoblast cells secreted various factors that may be important in maintaining the fetal allograft. Local inhibition of immune mechanisms and activation of suppressor lymphocytes by placental factor(s) make an attractive hypothesis, since they would minimize the risk of general immunosuppression that could produce adverse effects on both the fetus and mother during pregnancy. Our present findings suggest that suppressor T cells are perhaps produced by factors present in the trophoblastic fluids, although the specific role of components in trophoblastic fluid was not ascertained for this process in this study. Suppressor T cells are responsible for immunologic tolerance in various cells and are now considered essential in the homeostatic mechanisms for responsiveness against self-components. The trophoblast cells are also the site of synthesis for various specific proteins and steroidal hormones that are immunosuppressive.[6] Therefore a combination of various factors generated by trophoblast cell interface between the maternal and fetal compartments may be critical in local immunoregulation for maintenance of the fetal allograft.

We appreciate critical appraisal of the study by Dr. Fred S. Kantor. We thank Ms. Charline Johnson for her invaluable technical assistance in this study. We also thank Ms. Diana Ruffner for her assistance in preparing this manuscript.

Increased myometrial responsiveness to oxytocin during term and preterm labor

R. E. Garfield, PhD, and S. Beier, PhD
Hamilton, Ontario, Canada, and Berlin, West Germany

The contractile effects of oxytocin on the longitudinal and circular muscle of rat uteri from animals undergoing term and preterm labor were studied in vitro to define the action of the hormone. The maximal tension and slopes of oxytocin dose contractile–response curves, but not the pD_2 values ($-\log ED_{50}$), were higher in both muscle layers at term delivery and also during preterm delivery induced with antiprogesterones compared with responses from tissues of nondelivering animals. These data indicate that the myometrium is hyperresponsive and hyperreactive to oxytocin during term and preterm birth but not hypersensitive. The increase in oxytocin responsiveness of the myometrium may be fundamental to the initiation of labor and regulated by the increases in oxytocin receptors and postreceptor events, including gap junctions. (Am J Obstet Gynecol 1989;161:454-61.)

Key words: Myometrium, oxytocin, labor and delivery, parturition, gap junctions

Oxytocin, an octapeptide from the posterior pituitary, is recognized as a potent uterine stimulant that is thought to be essential for the contractile events of parturition.[1] Clinically, oxytocin is used extensively in obstetrics to increase the frequency and force of myometrial contractility. The initiation of term and preterm labor has been ascribed to the augmentation of myometrial responses to circulating levels of oxytocin brought on by an increase in oxytocin receptors present on the muscle cells and decidua[2-5] and also to the increase in gap junctions between the muscle cells (i.e., improved electrical coupling).[8-9] Several,[9-11] but not all,[12-14] studies in vivo and in vitro demonstrate that the myometrium is moderately more sensitive to oxytocin near the end of pregnancy. Differences in response to oxytocin of the longitudinal versus circular muscle layers are also recognized.[12-14] However, these studies are incomplete, since there are no pharmacologic studies of the effects of oxytocin on the myometrium undergoing either term or preterm labor when the receptors and gap junctions are at the highest levels.

This study clarifies the contractile effects of oxytocin on uterine strips from rats during labor and delivery at term and also preterm. Uterine tissues were obtained from nondelivering rats (days 17, 18, and 21 of gestation and also 1 day post partum), rats delivering spontaneously at term (day 22), and during preterm delivery (days 17 and 18) after treatment with one of three different antiprogesterone compounds (ZK 98.299 and ZK 98.734, Schering, Berlin, West Germany; RU 486, Roussel Uclaf, Romainville, France). The tissues, longitudinal and circular muscle strips, were mounted in muscle baths and the isometric force was recorded. Oxytocin was added cumulatively to the bath every 5 to 10 minutes to give final concentrations ranging from 10^{-11} to 10^{-5} mol/L. Dose-response curves were computed from the force developed by the tissue cross-sectional area per unit time. The maximum response (E_{MAX}), pD_2 value (i.e., $-\log ED_{50}$), and the slope of the dose-response curve were calculated for each tissue, and means for each group and differences between groups were estimated.

Material and methods

Timed-pregnant Wistar rats (Woodlyn, Charles Rivers, St. Constaint, Quebec, Canada) weighing about 300 gm were used. Animals treated with antiprogesterone agents were injected on the morning of the sixteenth day of gestation with either vehicle (controls) or one of the antiprogesterones (10 mg/kg) suspended in oil. At 24 (day 17) or 48 hours (day 18) after the antiprogesterone treatments, when, respectively, 10% to 70% of the fetuses were delivered, the animals were killed by a blow to the head. Similarly, animals were killed on day 22 of gestation during spontaneous birth (one to three fetuses delivered) or 24 hours post partum. After death the uteri were removed, opened down the mesometrial side, and pinned out in dishes with Krebs solution. Tissue strips (about 2 mm by 2 cm), either parallel or perpendicular to the long axis (i.e., representing longitudinal or circular muscle), were cut from

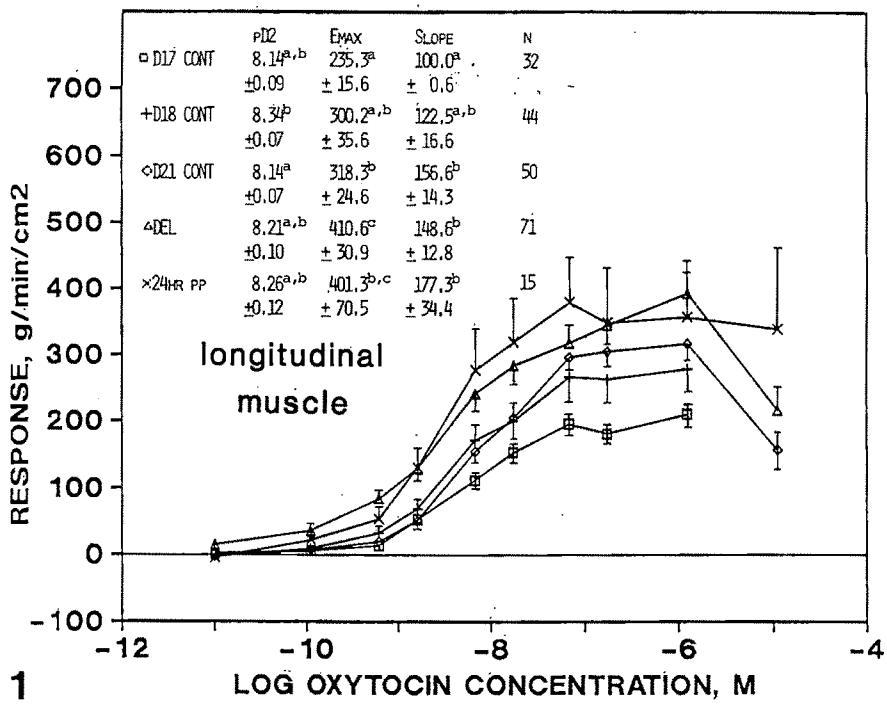

Fig. 1. Log oxytocin dose contractile–response curves for longitudinal uterine tissues from rats delivering spontaneously at term *(DEL)* and nondelivering at days 17, 18, and 21 *(D17, D18,* and *D21)* of gestation and postpartum *(pp)* (*bars* = SEM). Inserted values of pD_2, E_{MAX} (gm/min/cross-sectional area), and slope represent means for each group ± SEM (N = number of strips, four strips per rat). Values with different superscripts indicate significant differences ($p < 0.05$) between values.

the center of one uterine horn over fetal positions but not including the placenta regions.

The ends of the strips were tied with silk thread, and each strip was hung vertically in a 20 ml organ bath containing Krebs-Ringer solution oxygenated with 5% CO_2 and 95% O_2. The tissues were allowed to equilibrate for 20 minutes, and a resting force of 0.5 *g* was then placed on each strip. Force was monitored with Grass FT 30D isometric transducers connected to an eight-chananel Grass recorder. The mean force developed by the muscle strip per unit time was determined by measuring the area under the contraction curves with a microcomputer-linked digitizing tablet. The cross-sectional area of each tissue was estimated after the experiment from the wet weight of the strip (W), its length in the bath (L) and density (D) by means of the following formula:

$$\text{Area} = \frac{W}{L} \div D$$

The force developed by the tissue strip after adding the agonist minus the force of the spontaneous activity was taken as the tension developed in response to the agonist. The responses for each strip at each cumulative concentration of agonist were expressed as a percentage of the maximum response (E_{MAX}) and plotted against the log of the concentration of the agonist. Each dose-response curve was fitted to a third-order polynomial by microcomputer and the pD_2, ED_{20}, and ED_{50}, and ED_{80} values were obtained by interpolation. Mean estimates for E_{MAX} and pD_2 values were calculated for all strips within each group. The slope of the dose-response curve for each tissue was computed by measuring the slope of a line fitted to the ED_{20}, ED_{50}, and ED_{80} values. Means between groups were compared by a one-way analysis of variance or an unpaired Student *t* test. The mean forces generated/unit time/cross-sectional area for each dose of the agonist were plotted to produce the dose-response curves (Figs. 1 to 6).

Intact preparations of longitudinal myometrium in minimum essential medium (Gibco Laboratories, St. Lawrence, Mass.) with Hank's salts and 2 mmol/L Ca^{++} were pinned at the in vivo length and examined at 37° C with a Leitz-inverted microscope. Glass microelectrodes with resistances of 40 to 80 MΩ were used to record membrane potentials and measure input resistance (R_o) during smooth muscle cell impalements that were routinely maintained for 2 to 4 minutes. R_o is the point resistance to current flow from a cell during intracellular current injection and reflects the combined resistance of gap junctional and nonjunctional membrane, as well as (constant) myoplasmic resistance. R_o was determined during cell impalement from the voltage deflection of a previously bridge-balanced elec-

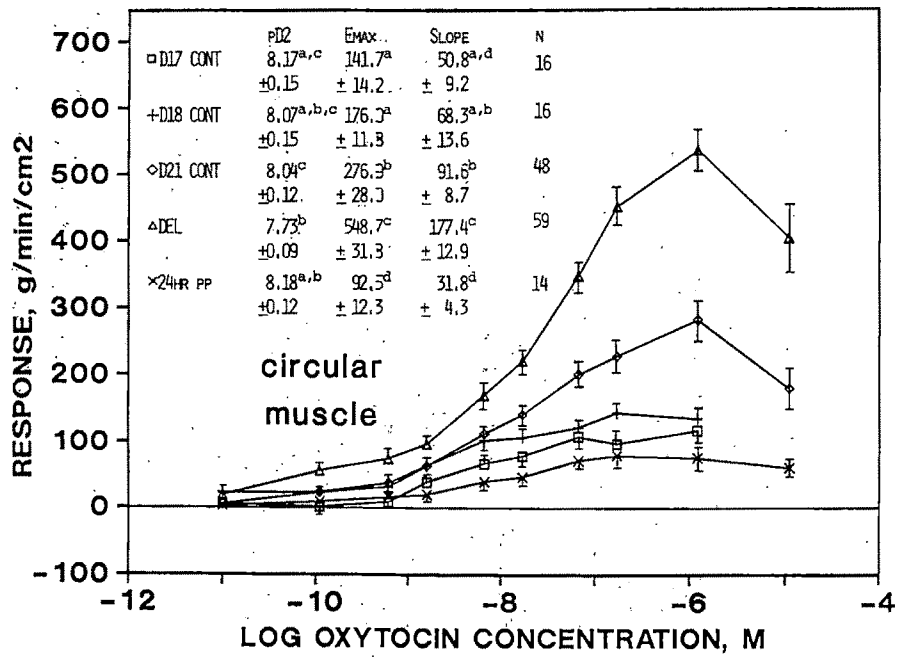

Fig. 2. Data as shown in Fig. 1 for circular uterine strips.

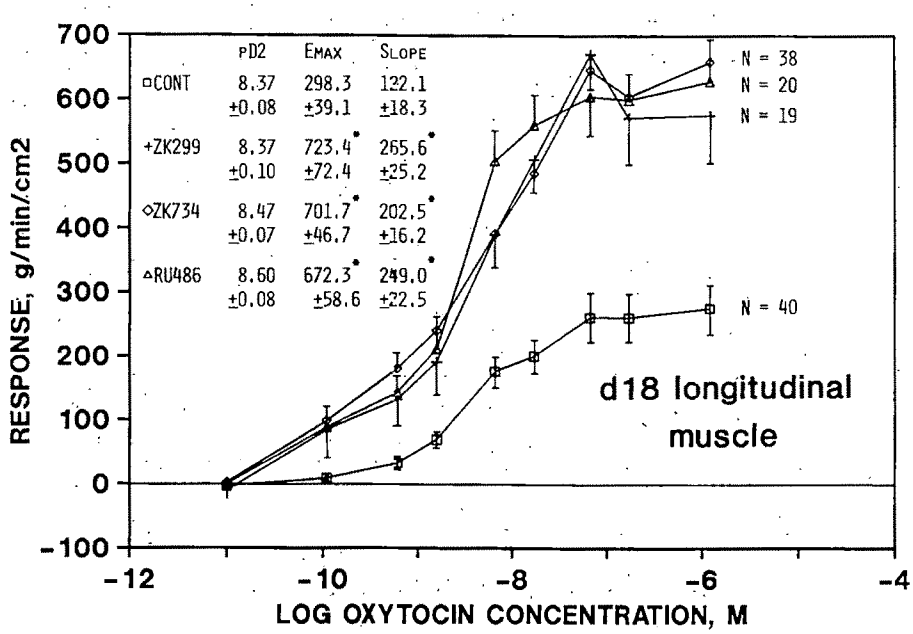

Fig. 3. Data as shown in Fig. 1 for longitudinal uterine tissues from control rats and animals delivering prematurely (about 70% of fetuses expelled) at day 18 of gestation after treatment with one of three different antiprogesterone compounds (ZK 299, ZK 734, and RU 486). *Significant differences between mean of control and treated.

trode to current injection (500 pA; 200 msec/sec). Values of membrane potential and R_o were retained only if the electrode returned to zero potential and bridge balance ± 1 MΩ upon removal from the cell.

Results

Oxytocin log dose contractile–response curves for longitudinal tissues from animals delivering at term and tissues from control animals at days 17, 18, and 21 of gestation and 1 day postpartum are shown in Fig. 1. Tissues from the delivering animals gave higher maximum responses compared with tissues from control nondelivering, preterm rats. The mean E_{MAX} values were significantly higher ($p < 0.05$) than those of the controls, but generally there were no differences in the pD_2 values or the slopes of the dose-response curves.

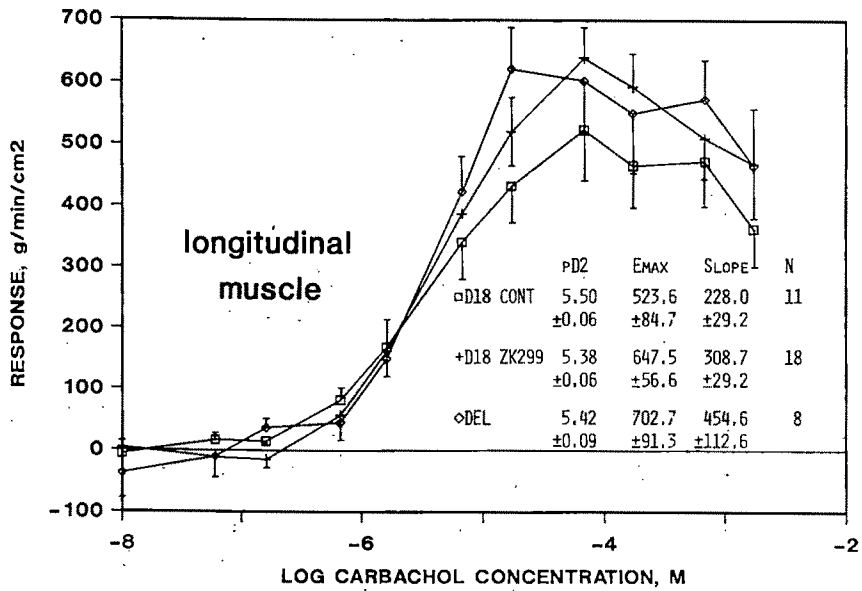

Fig. 4. Log carbachol dose contractile–response curves for longitudinal uterine strips from rats at day 18 nondelivering controls, day 18 delivering prematurely after ZK 299, and day 22 spontaneously delivering at term. There were no significant differences between means of pD_2, E_{MAX}, and slope values for the groups.

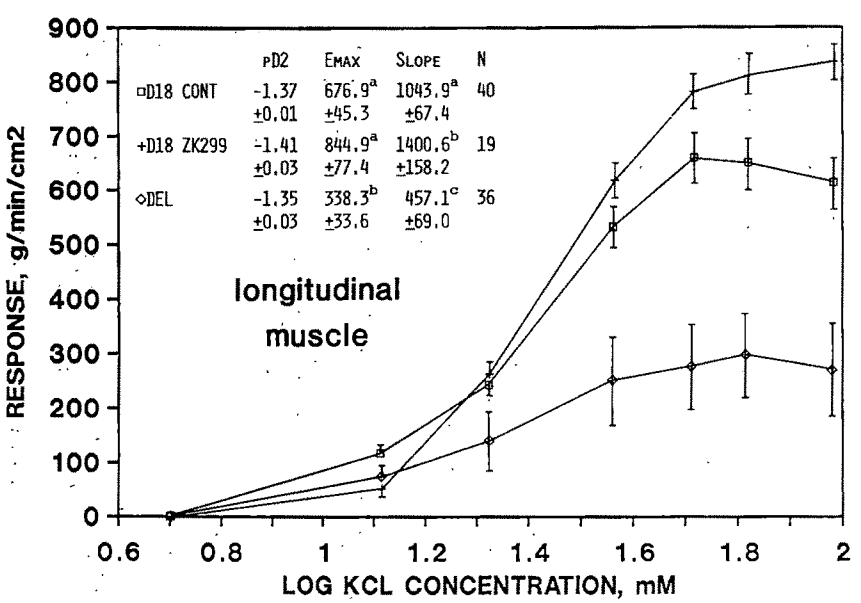

Fig. 5. Log KCl dose contractile–response curves for tissues from rats at day 18 nondelivering, delivering prematurely, and delivering at term. Mean values of pD_2, E_{MAX}, and slope with different superscripts show significant differences.

There were no differences between tissues from delivering versus postpartum animals. Fig. 2 shows the dose-response relationships for circularly cut myometrial strips from the same groups, as shown in Fig. 1. Again, there were no major changes in pD_2 values. However, the maximum responses (about two to four times as high) and also slopes of the dose-response curves were greater in tissues from term delivering rats than tissues from control rats at days 17, 18, and 21. In this case the mean values of E_{MAX} and slopes for tissues from postpartum animals were significantly reduced compared with those of delivering animals.

The dose-response relationships for longitudinal tissues from control nondelivering and preterm delivering rats at day 18 of gestation are illustrated in Fig. 3. The results from tissues of animals treated with each of the particular antihormones are comparable with those obtained from tissues during spontaneous delivery at term (Figs. 1 and 2). The maximum responses and slopes of the curves were significantly higher dur-

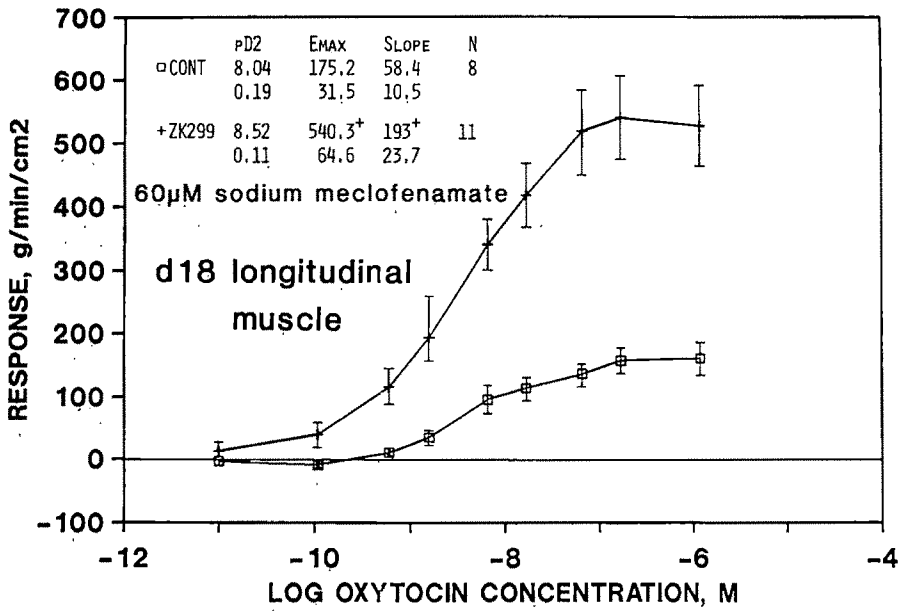

Fig. 6. Oxytocin dose-response curves from longitudinal uterine strips at day 18, nondelivering and delivering after ZK 299. All tissues were treated with 60 μmol/L sodium meclofenamate. Note that differences are similar to tissues not treated with the prostaglandin inhibitor (Fig. 3).

Table I. Resting membrane potential and input resistance in uterine longitudinal smooth muscle cells

	Membrane potential (mV ± SD) (n)	*Input resistance (R_o) (MΩ ± SD) (n)*
Delivering (term, day 22)		
Control	−40.5 ± 2.7 (101)	12.0 ± 4.8 (101)
1.2 mmol/L octanol	−39.8 ± 2.6 (90)	48.5 ± 15.2 (90)*
Wash (10 min)	−40.2 ± 1.9 (20)	11.6 ± 4.1 (20)
Preterm (nondelivering, day 21)		
Control	−42.6 ± 3.3	21.7 ± 11.10
Preterm (nondelivering, day 18)		
Control	−46.0 ± 3.0 (80)	24.1 ± 7.4 (80)
1 2 mmol/L octanol	−46.5 ± 2.4 (60)	49.0 ± 8.6 (60)*
Wash (10 min)	−46.9 ± 2.3 (20)	24.5 ± 4.9 (20)
Preterm (delivering, day 18), ZK 299 injected		
Control	−40.8 ± 2.7 (55)	13.8 ± 4.8 (55)
1.2 mmol/L octanol	−40.5 ± 2.4 (50)	44.3 ± 13.3 (50)*
Wash (10 min)	−41.3 ± 2.0 (15)	12.3 ± 5.3 (15)

*Significant differences ($p < 0.05$) from control values.

ing preterm birth induced with the antiprogesterones than in control tissues. Once more there were no significant differences in pD_2 values. Similar results were found in the circular muscle at day 18 and in both muscle layers at day 17 of gestation during the beginning of preterm birth in antiprogesterone-treated rats (data not shown).

The effects of carbachol and KCl on contractility of the myometrium were also studied to ascertain if the effects of other agents are also higher during term and preterm labor. Fig. 4 shows carbachol dose-responses for longitudinal tissues from day 18 nondelivering, day 18 delivering after ZK299, and day 22 spontaneous delivering rats. Unlike oxytocin, there were no significant differences in the carbachol dose-response curves. However, the maximum carbachol responses were similar to maximum values obtained with oxytocin during term and preterm delivery (Figs. 1 and 2). KCl responses, which were different from results with both oxytocin and carbachol, were lower in tissues from delivering term animals compared with tissues from nondelivering and preterm delivering animals at day 18 (Fig. 5).

To test if prostaglandin synthesis was involved in the

differences between delivering and nondelivering tissues in response to oxytocin, some tissues were treated with sodium meclofenamate (60 μmol/L) (Fig. 6). Again, the maximum responses and the slopes of the dose-response curves increased dramatically during preterm delivery after administration of ZK 98.299 compared with tissues from nondelivering animals. The responses were comparable with those obtained in the absence of the inhibition of prostaglandins (Fig. 3).

The effect of octanol, a specific gap junction uncoupling agent, on the contractile responses of oxytocin, KCl, and carbachol (not shown) was also studied. When added to the muscle baths, the alcohol eliminated spontaneous activity in a dose-dependent fashion and prevented the increase in contractility that is normally produced by the agonists. At 1.2 mmol/L octanol, even the highest concentrations of agonists failed to elicit a response (Fig. 6). When octanol was added to agonist-contracted tissue, relaxation occurred within about 3 minutes. The effect of the alcohol was immediately (about 5 minutes) reversible.

The resting membrane potential of longitudinal muscle tissues from delivering rats as measured with microelectrodes was -40.5 ± 2.7 mV from term animals and -40.8 ± 2.7 mV from preterm animals (Table I). These values were more depolarized than in tissues from nondelivering rats (-42.6 ± 3.3, day 21, and -46.0 ± 3.0, day 18), but the means of neither the delivering nor the nondelivering tissues were significantly different in the octanol-treated strips. However, input resistance was considerably higher after octanol compared with control values in tissues from both delivering and nondelivering animals. Oxytocin (10^{-8} mol/L) depolarized the resting membrane potential by a few millivolts both in the absence of octanol and also in its presence when membrane input resistance was elevated (data not shown).

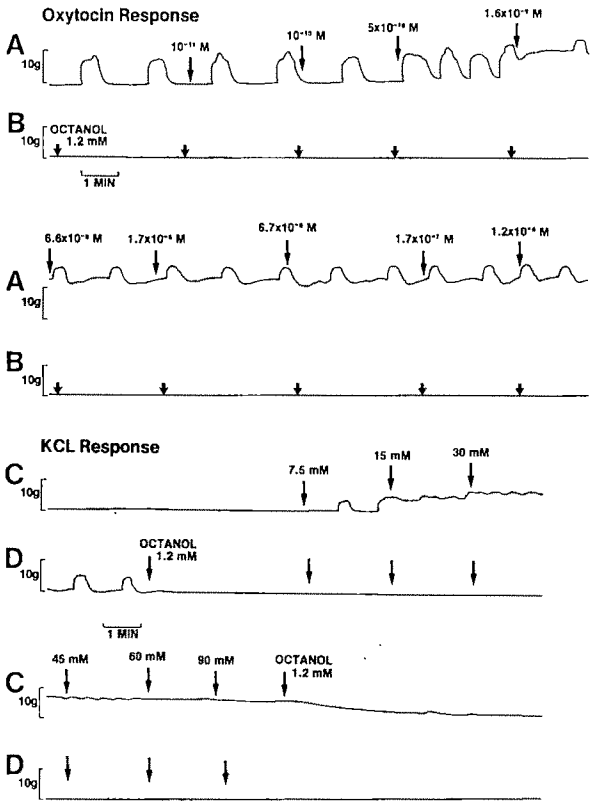

Fig. 7. Continuous tracings of longitudinal muscle (*strips A to D*) contractile responses to oxytocin (*top*) and KCl (*bottom*) in the absence (control) and presence of octanol.

Comment

The results of this study demonstrate unequivocally that the longitudinal and circular muscle layers of the myometrium are hyperresponsive (increased maximum response) and hyperreactive (increased slopes of dose-response curves) to oxytocin during term and preterm labor. During delivery both muscle layers develop two to four times or more tension in response to oxytocin than they do before delivery. The changes are particularly prominent in both muscle layers during preterm labor. However, there is no change in the sensitivity of the muscle to oxytocin, as would be reflected by a shift in dose-response curves and a change in pD_2 values. Moreover, the elevation in slopes and maximum responses is exclusively limited to oxytocin and not to the nonspecific stimulation of contractility observed with KCl or the effects of carbachol. These data suggest that the endocrine events that occur at term and those that arise from blocking the progesterone receptor with the antiprogesterones[15-17] increase either the effectiveness of the oxytocin-receptor interaction or a postreceptor mechanism to intensify the response. Such mechanisms might involve the number of receptors, the process by which receptor occupation influences contraction, or the extent of electrical coupling between cells. The increase in the ability of the myometrium to respond to oxytocin may be indispensable physiologically for the control of parturition. Furthermore, unless this change occurs before the pharmacologic application of the hormone, its effectiveness will be seriously restricted.

Numerous studies show that oxytocin receptor numbers in the uterus increase substantially at term in various animals and humans without a rise in plasma levels of the hormone.[1-5, 18, 19] These studies attribute the increase in receptors to changes in steroid hormone levels. An increase in the number of oxytocin receptors either at term or preterm after antiprogesterone treatment would increase either the sensitivity of the myometrium to oxytocin if spare receptors exist or intensify the maximum effects if there is no receptor reserve. Accordingly, the data in this study are consistent with

the supposition that there is little receptor reserve and that an increase in functional oxytocin receptors augments responsiveness to the hormone during term and preterm birth. Previous studies provide incomplete data on the effects of oxytocin on the myometrium during pregnancy, and none has shown dramatic increases in maximal effects as demonstrated in this study. Although in vivo studies indicate that the sensitivity to oxytocin may be raised at term, part of this may be attributable to the ability of oxytocin to stimulate the synthesis of excitatory prostaglandins[20, 21] and also the perception that the threshold dose (i.e., concentration that first initiates contractility above baseline) is lower during term (Fig. 1) and preterm birth (Fig. 3). The inhibition of prostaglandin synthesis with sodium meclofenamate (60 μmol/L) did not change the dose-response relationships in some experiments in this study (Fig. 6). Furthermore, none of the previous in vivo or in vitro studies has systematically examined the effects of oxytocin on tissues from delivering animals. Thus as shown by this study, the changes in the receptors or other events that occur during or immediately before delivery apparently contribute considerably to the ability of oxytocin to excite the muscle. These results add support to the hypothesis that the increase in oxytocin receptors may initiate labor not by raising the sensitivity to the hormone but by magnifying the force the muscle produces.

However, oxytocin receptor studies do not entirely agree with the information in this study. Oxytocin-binding sites to rat uterine tissues increase immediately before labor then decline to preterm levels within 1 day postpartum.[2] These data do not correlate with the action of oxytocin on the longitudinal muscle during term delivery and postpartum (Fig. 1: E_{MAX} gradually rises until delivery and does not fall postpartum), but they correspond to this study in regard to the circular muscle layer (Fig. 2: dramatic rise in oxytocin action occurs during delivery then falls postpartum). This may then indicate that the rise and fall in oxytocin receptor occur primarily in the circular muscle layer. Similar conclusions have been reached by Crankshaw[12] and Tuross et al.,[14] although they neither examined oxytocin effects during term delivery nor postpartum, and both studies did not determine oxytocin action during preterm delivery.

Since myometrial gap junctions (sites of electrical communication) are greatly increased during term parturition[6-8] and also during preterm birth after antiprogesterone treatment,[22] the increased responsiveness of the myometrium to oxytocin could be related in part to better electrical coupling between the muscle cells. The driving force for myometrial contractility is thought to be provided by propagated action potentials from pacemaker regions, and the frequency and intensity of contractions are, respectively, proportional to the regularity and duration of action potentials in each muscle cell and the total number of cells that are active.[23] Therefore an agonist that generates electrical activity or depolarizes the resting membrane potential may greatly augment the frequency of phasic contractile activity if the velocity of propagation of action potentials between cells is increased and amplify the contractile force by spreading further to recruit additional cells when gap junctions are increased. Similar increases in contractility to agonists have been observed in vas deferens after denervation and the appearance of gap junctions.[24] The fact that all responses to carbachol are similar (Fig. 4) to those of oxytocin during delivery (Figs. 1 to 3) when gap junctions are increased suggests either that this mechanism is not the sole system involved or that the two agonists have distinctly different actions. It is possible that either the location of agonist receptors (i.e., on all cells versus specific cells) is different or the pattern of contractility (i.e., phasic versus tonic contractions) varies with the agonist used.

However, like oxytocin receptors, gap junctions rise immediately before delivery and then decline rapidly within 1 day postpartum.[6, 7] Thus the data in this study (Fig. 1) are also not consistent with the hypothesis that the increase in gap junctions is responsible for the changes in responsiveness, at least in the longitudinal muscle layer during term delivery and postpartum. If so, during normal delivery at term, it is difficult to attribute changes in oxytocin receptors and gap junctions to the hyperresponsiveness of the longitudinal muscle during preterm delivery (Fig. 3). Nevertheless, there may be differences in the contractile significance of the presence of large numbers of gap junctions and oxytocin receptors between the longitudinal and circular muscle during term and early delivery. Furthermore, there may be distinctions in the functional states of the receptors (i.e., coupling to postreceptor events) and channels of the junctions (i.e., open or closed) between the two muscle layers at term and preterm.

The possible significant role of electrical coupling in the action of agonists was observed after the addition of octanol, an alcohol that closes pores in the gap junctions and electrically uncouples cells[25,26], it completely prevents contractions produced by oxytocin, KCl, and also carbachol (Fig. 7). Although a nonspecific inhibition of contractility by octanol cannot be excluded, it did not change the resting membrane potential but raised the input resistance (Table I). Large reproducible changes in input resistance were correlated with either the relative number of gap junctions at term and preterm[6, 22] or the presence of octanol, which is known to specifically increase junctional resistance.[25, 26] Therefore these changes in input resistance are thought to

reflect predominant changes in junctional coupling (i.e., a decrease in R_o when junctions develop during term and preterm delivery and an increase when the junctions reversibly close in response to octanol). These data are interpreted to mean that cell-to-cell communication is necessary for spontaneous and agonist-induced contractility.

The selective increase in responsiveness of both layers of the myometrium to oxytocin during term and preterm delivery may be essential for labor and is probably imparted by the specific increase in oxytocin receptors, changes in postreceptor mechanisms, and to enhanced electrical coupling. The absence of change in the maximum capacity of the myometrium to contract between preterm nondelivery and delivery at term or preterm, provided the tissue is challenged appropriately (i.e., carbachol at any time and oxytocin during delivery), suggests that no change occurs in the force-generating potential of the myometrium. The maximum response to KCl is diminished during term delivery and is lower than responses observed with oxytocin or carbachol. This result remains to be explained but may be the result of an inhibition of the muscle electrogenic Na^+ to K^+ pump by some system at term and the depolarization of the muscle (Table I) during delivery. Octanol inhibits spontaneous and agonist-stimulated contractions, indicating that electrical coupling may be required for contractions of the myometrium.

We thank Walter Elger, Schering, and D. Philibert, Roussel, for the antiprogesterone compounds, Ms. D. Merrett for technical assistance, and my colleagues, Drs. M. S. Kannan, D. J. Crankshaw, and L. Branda, for reading the manuscript, and Dr. M. Blennerhassett for help with the microelectrode measurements.

CA 125 in the epithelium closely related to the embryonic ectoderm: The periderm and the amnion

Yoshihiko Nanbu, MD, Shingo Fujii, MD, Ikuo Konishi, MD, Hirofumi Nonogaki, MD, and Takahide Mori, MD

Kyoto, Japan

The amnion is believed to be derived from either cytotrophoblastic cells or embryonic ectoderm. However, it produces and secretes CA 125, which is considered a differentiation antigen of fetal coelomic epithelium derived from the mesoderm of germ cells. To verify this, the immunohistochemical localization of CA 125 in human fetal tissues (between 7 and 23 weeks of gestation) derived from the ectoderm, endoderm, or mesoderm, and in the fetal membranes and placenta was studied. Among the mesoderm-derived tissues, only the fetal coelomic epithelium–related tissues were positive for anti-CA 125 from 15 weeks of gestation. The endoderm-derived tissues did not react with anti-CA 125. However, among the ectoderm-derived tissues, only the periderm reacted with anti-CA 125 from 7 weeks until it sloughed from the stratum intermedium by 23 weeks of gestation. Among the fetal membranes and placenta, only the amnion reacted with anti-CA 125 from 9 weeks to term. These findings indicate that the amnion and the periderm, both of which constitute the epithelia covering the amniotic cavity, in addition to the fetal coelomic epithelium-related tissues, produce CA 125. (AM J OBSTET GYNECOL 1989;161:462-7.)

Key words: CA 125, immunohistochemistry, amnion, periderm, ectoderm

CA 125 is an antigenic determinant recognized by a monoclonal antibody OC 125 against an ovarian cancer cell line (OVCA 433).[1] An assay of serum CA 125 has been shown to be useful for the diagnosis and monitoring the course of patients with ovarian cancer.[2] However, serum CA 125 levels increase not only in women with other gynecologic malignancies,[3] but also in women with benign conditions such as endometriosis,[4] pelvic inflammatory diseases,[5] and during pregnancy.[6] Immunohistochemically, the CA 125 antigen is detected in the coelomic epithelium–related tissues; pleura, pericardium, peritoneum, and müllerian ducts of the fetus[7]; and müllerian-derived epithelia of the adult such as tubal, endometrial and endocervical epithelium.[8] Therefore CA 125 is considered a differentiation antigen associated with fetal coelomic epithelium and its derivatives,[7] which are believed to be derived from the mesoderm of germ cells.

Amniotic fluid contains a large amount of CA 125.[9] We recently demonstrated by immunohistochemical and biochemical studies that both the decidua and the amnion can produce CA 125.[10] Nevertheless, the amniotic cavity, which develops by cavitation within the inner cell mass of germ cells, is formed with the floor of the embryonic ectoderm and the roof of the amnion, which is thought to be derived from cytotrophoblastic cells.[11] In addition, the flattened amniotic cells are continuous with the embryonic ectoderm, and are alternatively called the amniotic ectoderm.[11] Moreover, the amniotic cells are now thought to arise from the periphery of the embryonic ectoderm.[12, 13] Consequently, it is unclear why the amnion produces and secretes CA 125. Therefore we examined the immunohistochemical localization of CA 125 in human fetal tissues derived from the ectoderm, endoderm, or mesoderm and in the fetal membranes and placenta.

Material and methods

Fresh specimens of various fetal tissues were obtained from human fetuses (three female fetuses at 9, 17, and 23 weeks of gestation, four male fetuses between 15 and 17 weeks of gestation, and one fetus of unknown sex at 7 weeks of gestation) at legal elective abortions; the tissues listed in Table I were used for the study. Informed consent was obtained to study the fetuses. Tissues of the amnion, chorion, and decidua between 9 and 40 weeks of gestation obtained at either legal elective abortions or spontaneous deliveries were also used for this study.

All tissue were snap-frozen in Tissue-TEK OCT compound (Ames Co., Elkhart, Ind.) and stored at −70° C. Four-micrometer cryostat sections were prepared from each specimen and stored at −20° C until use. The immunohistochemical staining of CA 125 with primary antibody OC 125 was performed with a CIS His CA 125 staining kit (Oris, Saclay, France) according

to the manufacturer's instructions. The sections were treated with 3% hydrogen peroxide and incubated with antibody (diluted with 3 ml of phosphate-buffered saline solution according to the manufacturer's instructions) at 4° C overnight. The sections were then treated with anti-mouse IgG-biotin complex followed by avidin-peroxidase complex, and were stained with 3-amino-9-ethylcarbazole solution with 0.15% hydrogen peroxide. The sections were counterstained with hematoxylin. For the negative controls, normal mouse serum or phosphate-buffered saline solution was used instead of each primary antibody. For the positive controls, the sections of ovarian serous carcinoma with high levels of serum CA 125 were used.

Results

Ectoderm-derived tissues (Table I). The periderm of the fetuses at 7 and 9 weeks of gestation was moderately positive for anti-CA 125 in the cytoplasm (Fig. 1). The periderm of the fetuses at 15 (Fig. 2), 16, and 17 weeks of gestation were strongly positive for anti-CA 125 in the cytoplasm irrespective of sexual differentiation. However, the stratum intermedium beneath the periderm did not react with anti-CA 125. At 23 weeks of gestation, cells of the periderm were already sloughed from the straum intermedium, and the latter constituted the epidermal layer of the skin. Therefore at this stage the fetal skin was negative for anti-CA 125 (Fig. 3).

The other ectoderm-derived tissues such as the central nervous system and neural crest derivatives were negative for anti-CA 125.

Endoderm-derived tissues (Table I). The endoderm-derived tissues such as the lung, intestine, and urinary bladder did not react with anti-CA 125 in any fetus examined.

Mesoderm-derived tissues (Table I). In the female fetuses of both 17 and 23 weeks of gestation, epithelial

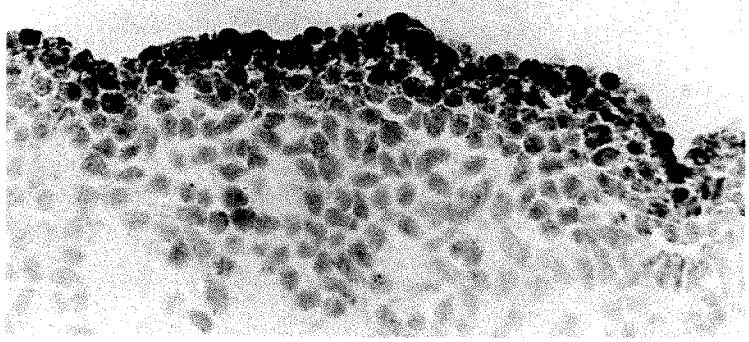

Fig. 1. Immunohistochemical staining is moderately positive with anti-CA 125 in the cytoplasm of the periderm at 9 weeks of gestation. (Original magnification ×400.)

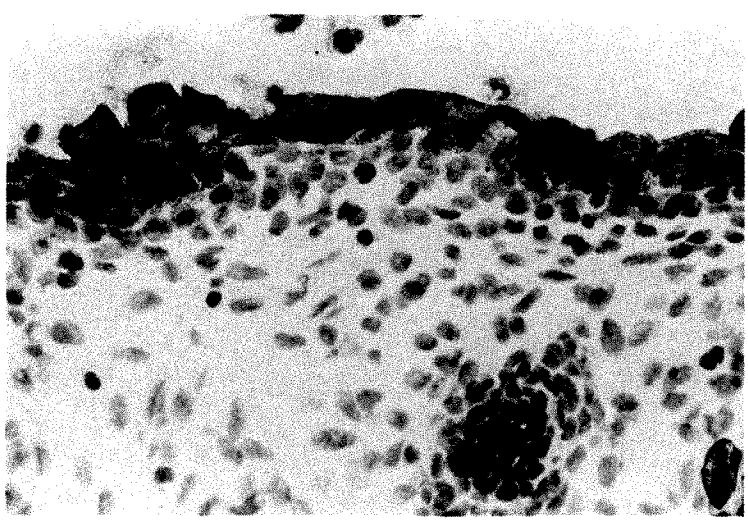

Fig. 2. The periderm at 15 weeks of gestation is strongly reactive with anti-CA 125 in the cytoplasm. (Original magnification ×400.)

cells of the uterine cervix, corpus, and fallopian tube (Fig. 4) were weakly positive for anti-CA 125, whereas the surface epithelium of the fetal ovary was negative. Fetal coelomic epithelium-derived epithelia such as the pleura, pericardium (Fig. 5), and peritoneum were faintly positive for anti-CA 125 in both female and male fetuses between 15 and 23 weeks of gestation. Reactivity was observed along the luminal surface and in the apical portion of the cytoplasm. However, these tissues at 7 and 9 weeks of gestation were negative for anti-CA 125.

The mesoderm-derived tissues, which were not associated with the fetal coelomic epithelium, were negative for anti-CA 125.

Fetal membranes (Table I). The amniotic epithelium of the fetal membranes at gestational ages between 9 and 40 weeks was strongly positive for anti-CA 125 (OC 125), not only along the luminal surface and in the apical portion of the cytoplasm, but also as accumulations of atypical coarse granules of chromogen deposits in the cytoplasm (Fig. 6).

The chorionic epithelium of the fetal membranes at any stage examined in this study was negative.

Placenta (Table I). Both cytotrophoblast and syncytiotrophoblast did not react with anti-CA 125 in all the placentas examined.

Comment

Our study demonstrated that CA 125 is present in fetal coelomic epithelium and its derivatives after 15 weeks of gestation. However, it is usually only weakly positive for anti-CA 125 until 23 weeks of gestation. In addition, we found that both the amnion and the per-

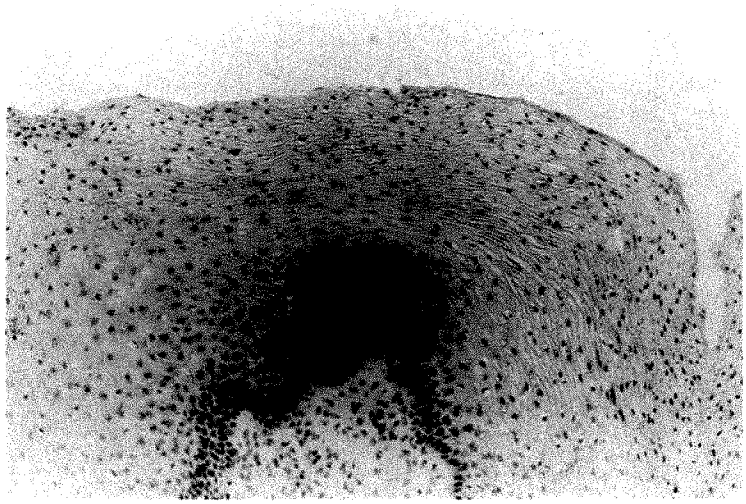

Fig. 3. Fetal skin at 23 weeks of gestation sloughs off the periderm, and the dermis shows negative staining for anti-CA 125. (Original magnification ×100.)

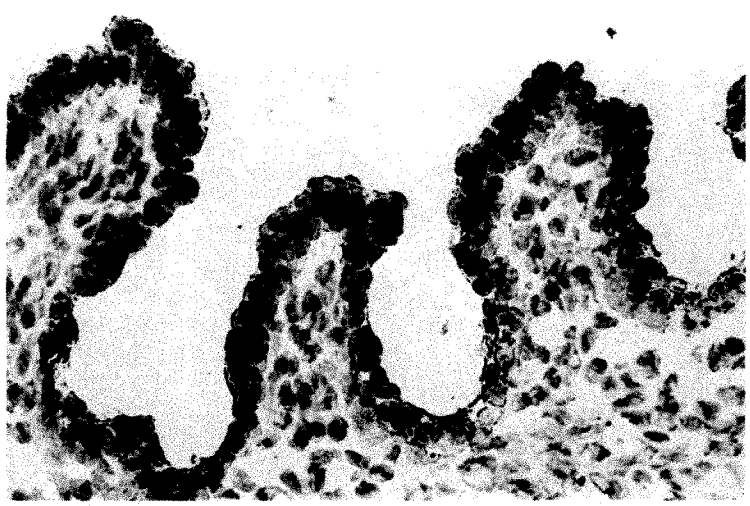

Fig. 4. The fallopian tube at 17 weeks of gestation is reactive with anti-CA 125 along the luminal surface and in the apical portion of the cytoplasm. (Original magnification ×200.)

iderm are positive for anti-CA 125 from 7 weeks of gestation. Thereafter, the periderm is strongly positive for anti-CA 125, and it sloughs from the stratum intermedium by 23 weeks of gestation. The amnion was positive for anti-CA 125 until the end of pregnancy. However, other tissues derived from the ectoderm, mesoderm, and endoderm were negative for anti-CA 125. Moreover, both cytotrophoblasts and syncytiotrophoblasts were negative for anti-CA 125 throughout gestation.

The amnion was reported to be the source of CA 125 in the amniotic fluid.[9] The amniotic cells are continuous peripherally with the embryonic ectoderm, and the latter forms the floor of the amniotic cavity.[11, 12] The periderm is derived from the embryonic ectoderm. Therefore our findings demonstrate that the epithelia covering the amniotic cavity produces CA 125. In addition, the positivity for anti-CA 125 in the amnion and the periderm occurs earlier in embryonic life and is stronger than that of fetal coelomic epithelium and its derivatives. This suggests that CA 125 is not a differentiation antigen that is confined to fetal coelomic epithelium and its derivatives, but rather it is a primitive antigen in the epithelia that is closely related to the embryonic ectoderm such as the periderm and the amnion. However, the primitive streak that originates from the embryonic ectoderm forms the mesoderm of the embryo, and the latter produces fetal coelomic epithelium.[11] Therefore, a connection arises between the embryonic ectoderm and fetal coelomic epithelium.

Although the biologic significance of CA 125 remains unclear, the production of CA 125 from the periderm

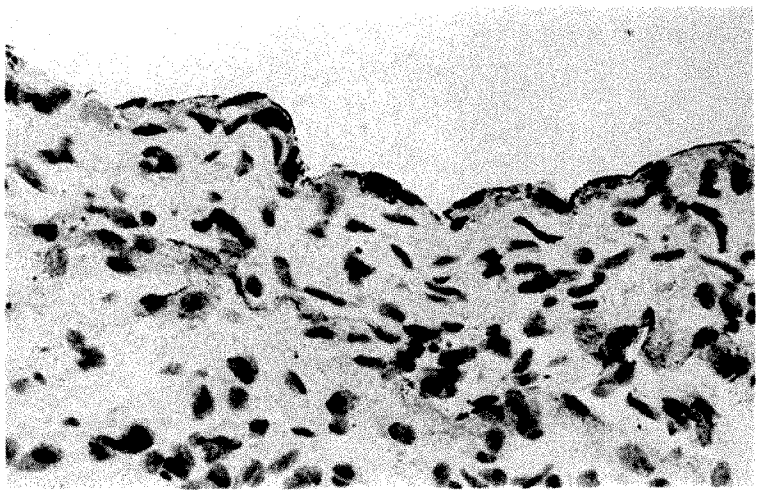

Fig. 5. Pericardium at 15 weeks of gestation is reactive with anti-CA 125 in the apical portion of the cytoplasm. (Original magnification ×400.)

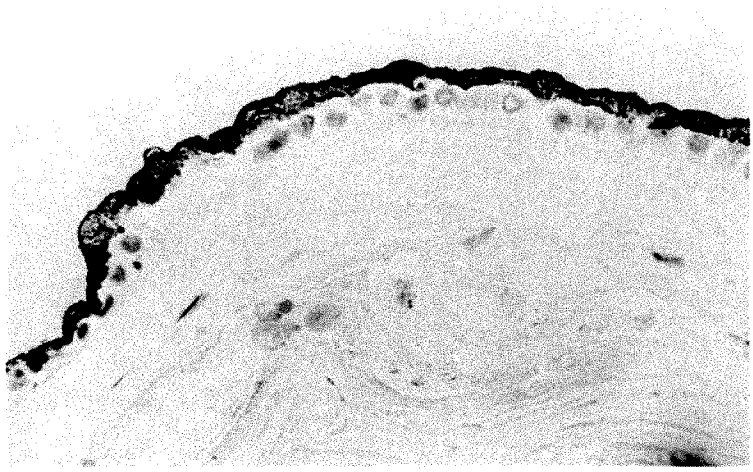

Fig. 6. Amniotic epithelium at 37 weeks of gestation is reactive with anti-CA 125 not only along the luminal surface and in the apical portion of the cytoplasm but also in the cytoplasm. (Original magnification ×400.)

suggests that a high-molecular-weight glycoprotein expressing an antigenic determinant CA 125 may be a primitive substance that covers the skin, at least until midgestation when the periderm is replaced by the vernix caseosa.[11] In contrast, the fetal coelomic epithelium and its derivatives begin to synthesize CA 125 during differentiation into adult müllerian epithelium. Conversely, fetal coelomic epithelium, which is derived from the primitve streak of the ectoderm, may begin to produce CA 125 when it differentiates into cells resembling the stage of cells of the periderm or amnion.

With regard to the production of CA 125 in neoplastic tissues, serous carcinomas of the ovary usually show an increased secretion of CA 125,[2] but most adenocarcinomas of the uterine cervix show a reduced secretion of CA 125.[8, 14] Although it is unknown whether the epitopes of CA 125 glycoprotein molecules produced by neoplastic tissues are equivalent to those of normal tissues, neoplastic tissues may have some acquired genetic abnormality in either the production or secretion of CA 125.

Power spectrum analysis of myometrial electromyogram and intrauterine pressure changes in the pregnant rhesus monkey in late gestation

Hsing Wen Hsu, BS, Jorge P. Figueroa, MD, PhD, M. Barbera O. M. Honnebier, MD, Richard Wentworth, PhD, and Peter W. Nathanielsz, MD, PhD

Ithaca, New York

Various methods have been used to quantify myometrial activity in the pregnant rhesus monkey during the last third of gestation. A precise definition of activity must retain the characteristics of epoch duration, amplitude, and the repetitive frequencies of active epochs. We used Fast Fourier Transform and power spectrum analysis to determine whether the patterns of myometrial contractility consist predominantly of contractions or contractures. This analysis allows quantification of activity represented by each of these patterns of activity. We applied these methods to myometrial electromyogram and intrauterine pressure recordings in pregnant rhesus monkeys to characterize the changes in myometrial activity that occur after surgery, after intravenous indomethacin administration, and when food is withdrawn for 48 hours. We conclude that changes in the frequency pattern of myometrial activity provide important information in relation to labor and delivery contractions. (Am J Obstet Gynecol 1989;161:467-73.)

Key words: Power spectrum analysis, myometrial activity, uterine electromyogram

Various methods have been used in experimental animals to characterize and quantify myometrial activity throughout pregnancy.[1-9] The pregnant rhesus monkey has been extensively investigated to study changes in myometrial activity and responses to various physiologic and pharmacologic agents. Myometrial electromyogram electrodes and sensors for measuring intrauterine pressure can be placed in this species at the beginning of the last third of gestation. Several groups of investigators have shown varying degrees of activity at different times of the 24-hour day during various stages of gestation.[5, 10, 11] These cycles of myometrial activity have a clear temporal relationship to the circadian hormone changes in maternal and fetal plasma.[10, 12]

Epochs of myometrial activity differing in duration and intensity have been described in pregnant sheep

and monkeys.[2-4] One method of assessing the nature of activity at any moment is to characterize duration and amplitude of each individual event of myometrial electromyogram activity or intrauterine pressure change, either together or separately. In the sheep we have described computer-based methods for the determination of duration of individual epochs of activity.[6] In sheep, throughout the majority of gestation the most common epochs of myometrial activity are contractures, which we have defined as long duration epochs of increased intrauterine pressure or electromyogram activity lasting longer than 3 minutes.[3, 4, 6, 13] During labor and at delivery, myometrial activity shows a contraction pattern during which the epochs of activity are shorter than 2 minutes.[13] To obtain a clear impression of the type of myometrial activity under different physiologic conditions, contractures must be distinguished from labor and delivery contractions. Assessment of myometrial activity as Montevideo units or area of activity under a pressure curve does not permit such a distinction because in the use of these methods important information regarding duration and frequency of individual epochs of activity is lost.

Fast Fourier Transform and power spectrum analysis are alternative methods for studying waveforms that have repetitive frequencies. The Fast Fourier Transform represents the decomposition of the waveform under study into its frequency components. Fast Fourier Transform also permits assessment of amplitude of the peaks that occur with the different frequencies. The retention of amplitude characteristics and division of all observed activity epochs into repetitive frequencies at different frequency ranges allows greater description of patterns of myometrial activity than analyses based solely on counts of individual epochs of activity or Montevideo units or computed area under the curve of the raw electromyogram or intrauterine pressure signal. Depending on the rate of sampling and the frequency of the waveform, Fast Fourier Transform and power spectrum analyses can be performed over variable periods of time appropriate to the experimental question under study. Thus myometrial activity for many hours at different times of the day on successive days or for short periods after administration of various drugs can be compared.

The purpose of this study was to determine whether Fast Fourier Transform and power spectrum analysis of uterine electromyogram and intrauterine pressure make possible rapid distinction of different patterns of myometrial activity. In particular, we wanted to determine whether these methods permit clear distinction of contraction activity that is characteristic of labor and delivery. We performed Fast Fourier Transform and power spectrum analysis of both myometrial electromyogram and intrauterine pressure in the pregnant rhesus monkey obtained during three different situa-

tions: immediately after operation, after food withdrawal, and during treatment with the prostaglandin synthetase inhibitor indomethacin. The results permit a direct comparison of myometrial electromyogram and intrauterine pressure that is important in the assessment of the many previous studies in which only one of these two variables was measured.

Methods

Care of animals

Surgical procedures. Ten pregnant rhesus monkeys of known gestational age were obtained from the California Regional Primate Center, Davis, Calif., and were acclimated to the laboratory conditions as previously described.[11, 14] The animals were housed in rooms with controlled light cycles (14:10 hours light-dark) with lights on at 8 AM. Purina 5045 Monkey Chow and fresh fruits were provided. Water was provided ad libitum during the experimental period. At the time of operation monkeys ranged from 92 to 107 days' gestational age. Animals were instrumented with techniques described previously.[5, 11, 14] Briefly, with the animals under halothane anesthesia, catheters were placed in the maternal femoral artery and vein in all 10 animals. In each animal, two pairs of myometrial electromyogram leads were placed on the anterior wall of the uterus. In six animals, two catheters made of Tygon microbore tubing (Norton Performance Plastics, Akron, Ohio) (inner diameter 1.27 mm; outer diameter 2.29 mm), with a side hole 1 cm from the tip, were placed with 3 to 6 cm of the catheter within the amniotic cavity. A small retaining collar of Tygon prefabricated around the catheter was located just within the uterus. Heparinized arterial blood samples were drawn at 10 AM, 3 PM, and 9 PM on most days for various hormonal analyses (data not reported). No experimental intervention was initiated for at least 5 days after operation.

Indomethacin protocol. In one animal that was having spontaneous contractions at 132 days' gestation, Indocin (Merck, Sharpe and Dohme) was administered via the maternal inferior vena caval catheter at an infusion rate of 6 mg/hr starting at 3:30 PM and ending at 9 PM.

Food withdrawal protocol. On days that animals were fed, fresh food was provided at 8 AM and the monkey was allowed to feed freely. Three animals were used in the food withdrawal protocols. Food was removed at 3 PM and the next 24-hour period was called the first day of food withdrawal. Food was offered freely after exactly 48 hours of food withdrawal. Only the electromyogram was recorded in the food withdrawal protocol.

Recording of electromyogram and data storage. The uterine electromyogram was recorded from multistranded bipolar stainless steel wires (Cooner AS 632) implanted 3 to 5 mm apart on at least two sites of the

myometrium.[5, 11, 14] One of the intraamniotic catheters was connected to a pressure transducer (Cobe Lakewood, Colo.) that was placed in a small box on the monkey's back beneath the jacket. Acquisition of the myometrial electromyogram and intrauterine pressure waveforms was performed with a custom-built computer-based data acquisition system previously described in detail.[6] Briefly, the signals (electromyogram and intrauterine pressure) were sampled at 32 Hz, digitized, and the average value over 8 seconds was stored on tape with a time signal. The initial sampling frequency of 32 Hz prevented aliasing problems with changing signals. The lower storage rate of the one reading every 8 seconds represented the averaged data and created a manageable volume of data for subsequent analysis.

Data analysis. Fast Fourier Transform and power spectrum analysis were performed on the digitized intrauterine pressure and electromyogram data by means of the Asyst 2.0 program.[15] Integration of the area under the curve for the power spectrum was performed by addition of all data points for the chosen range of cycle frequencies.

Statistical analysis. In the food withdrawal protocol, the integrated power spectrum data were analyzed by Student's paired t test after one-way analysis of variance. The paired t test was used only for comparison of the increment between the control period (either daylight or darkness) and the same period on the second day of food withdrawal (either daylight or darkness). The effect of the treatment was considered statistically significant when $p < 0.05$. Data obtained during hours of daylight and hours of darkness were analyzed separately and were not compared to each other.

Results

Determination of power spectrum frequency windows. In six animals the power spectrum of either intrauterine pressure and/or electromyogram or both were analyzed for frequencies between 0.01 and 0.8 cycles/min. Because there were no differences between power spectra of intrauterine pressure or electromyogram data in the different frequency windows (Figs. 1 and 2), data for percentage power in different windows of the intrauterine pressure and electromyogram spectra were pooled for analysis of different patterns of contraction and contracture activity (Table I) to determine the percentage of total power at frequencies above and below three different cutoffs (0.11, 0.2, and 0.25 cycles/min). Data were obtained from animals in the first 5 days after operation and were divided into periods when, by visual inspection, the activity consisted primarily of contractions and when activity consisted primarily of contractures (Table I). After evaluation of these data, quantification of contracture activity was performed on frequencies in the window 0.01 to 0.11 cycles/min (i.e., <1 cycle every 9 minutes) and contractions on frequencies in the window 0.2 to 0.8 cycles/min (i.e., >1 cycle every 5 minutes).

Power spectral analysis of contractions. Fig. 1 shows the raw data trace for intrauterine pressure and electromyogram at a time when only contractions occurred. The good correspondence between intrauterine pressure and electromyogram can readily be seen. For the electromyogram recording shown, 94.8% of the activity in repeating frequencies was at a rate >1 every 5 minutes (a frequency >0.2 cycles/min). For the intrauterine pressure recording shown, 97.1% of the activity in repeating frequencies occurred at rates >1 every 5 minutes.

Power spectral analysis of contractures. Fig. 2 shows the raw data trace for intrauterine pressure and electromyogram at a time when only contractures occurred. The good correspondence between intrauterine pressure and electromyogram can readily be seen. For the electromyogram activity in the recording shown, 66.4% of the activity in repeating frequencies was at frequencies lower than 1 every 9 minutes (a frequency <0.11 cycles/min). For the intrauterine pressure in the recording shown, 83.5% of the activity in repeating frequencies occurred at rates <1 every 9 minutes.

Indomethacin effect. Fig. 3 shows the change in the power spectrum of intrauterine pressure and myo-

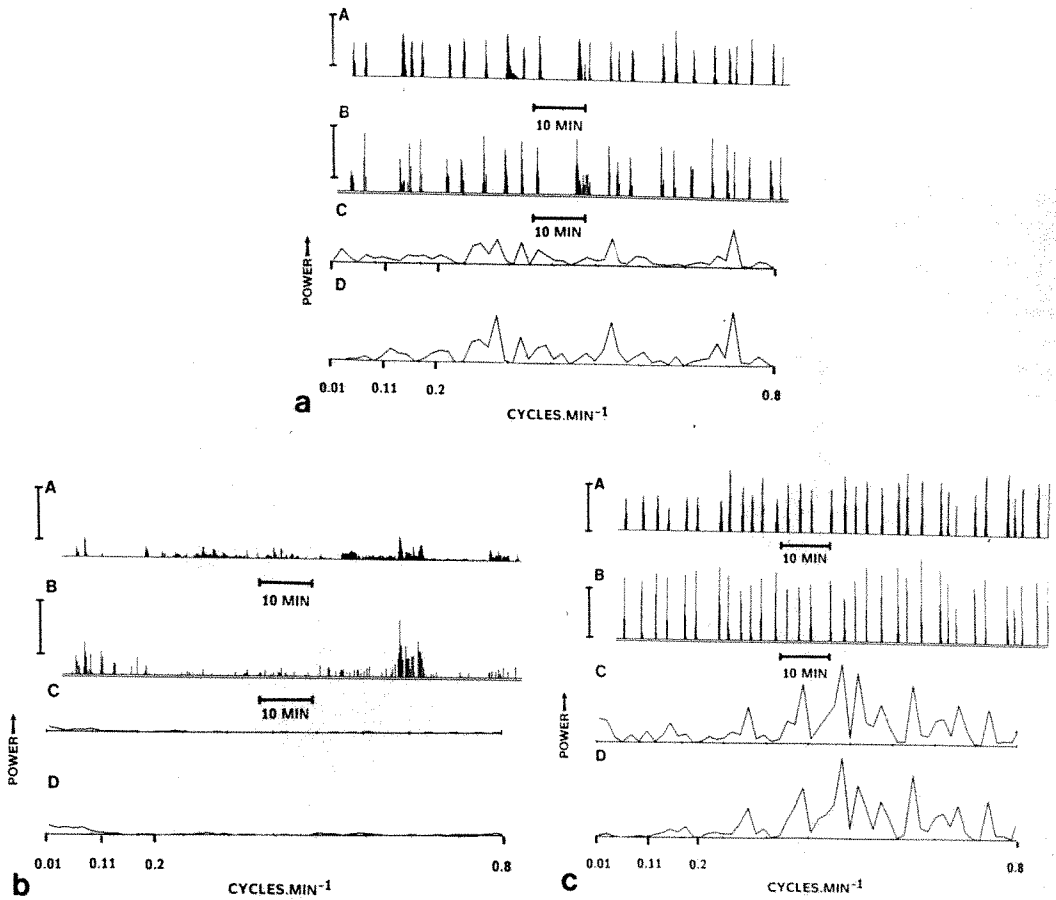

Fig. 3. Myometrial electromyogram and intrauterine pressure in a pregnant rhesus monkey 132 days' gestational age and 20 days after operation taken between 2 PM and 11:30 PM. **a,** Before indomethacin. **b,** During indomethacin infusion at 6 mg/hr via the maternal aorta. **c,** After cessation of indomethacin infusion. *A,* Intrauterine pressure recording: calibration bar 10 mm Hg; *B,* Myometrial electromyogram at the same time as *A*; calibration bar 50 μV. The running mean threshold baseline has been removed in both *A* and *B*. *C,* Power spectral analysis of intrauterine pressure recording in *A*. *D,* Power spectral analysis of electromyogram recording in *B*.

metrial electromyogram after a pregnant monkey that was having spontaneous contractions was treated with indomethacin (Fig. 3, *a*). During the period of indomethacin treatment, the majority of the power in the spectrum for both intrauterine pressure and electromyogram shifted to the low-frequency range (Fig. 3, *b*), but after the contractions returned, the power spectrum shifted back to the high-frequency range (Fig. 3, *c*).

Food withdrawal. The nighttime power spectrum for electromyogram in one animal the night before food withdrawal is shown in Fig. 4, *A*. The majority of the spectral power is at frequencies <1 cycle every 9 minutes. On the second night of food withdrawal, the power spectrum shifts to high frequency (Fig. 4, *B*); after food is returned, the spectrum shifts back to low frequency (Fig. 4, *C*). Fig. 5 shows the total power in the contracture and contractions portions of the power spectrum before, during, and after the food withdrawal for daylight and darkness portions of the 24-hour period. By the second night of food withdrawal the activity in the contractions portion of the power spectrum had risen to 660% of the second control day ($p < 0.05$). There was no change in the contractures spectrum. Power spectrum during daylight hours was analyzed on control day 2, food withdrawal day 2, and recovery day 2 in the three animals that had food withdrawn. On the second food withdrawal day the contractions portion of the power spectrum had risen to 270% of the second control day ($p < 0.05$). This represents a much smaller increase than during the hours of darkness. The contractures portion of the power spectrum also increased significantly above that on control day 2 (Fig. 5).

Comment

Figs. 1 and 2 demonstrate the excellent correspondence between the power spectra of intrauterine pressure and electromyogram. It is sometimes impossible to obtain good intrauterine pressure recordings from

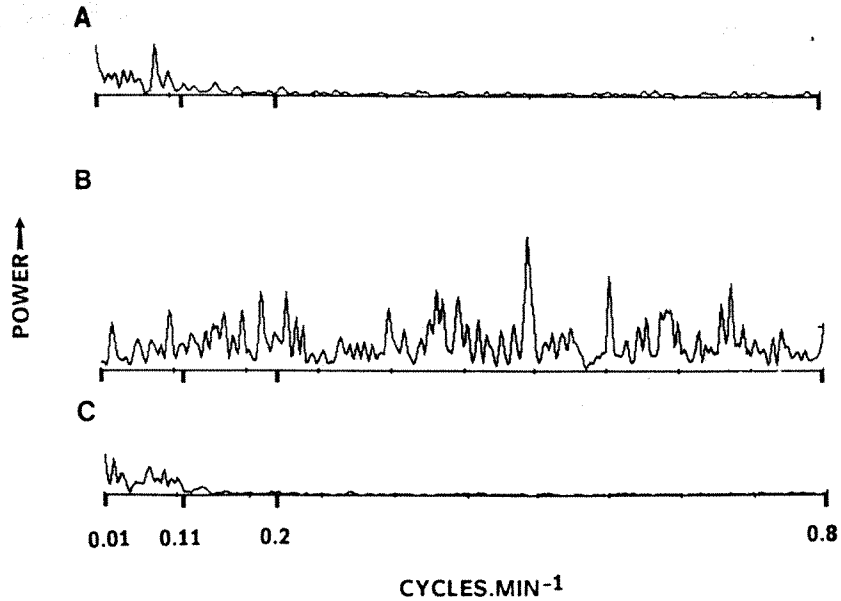

Fig. 4. Electromyogram data from an instrumented pregnant rhesus monkey at 127 to 133 days' gestational age and 28 to 34 days after operation. pregnant animals. Movement artifacts (e.g., crouching and straining at stool) produce artificial changes in intrauterine pressure that can only be distinguished from myometrial activity if simultaneous electromyogram is recorded. In addition, in some experimental paradigms it is preferable not to incise the uterus. Thus it is reassuring that recordings of electromyogram over several hours have good correspondence to the information obtained from intrauterine pressure. Our studies with the pregnant sheep show that individual electromyogram complexes may not be accompanied by changes in intrauterine pressure because electromyogram activity before labor may not be propagated over the whole uterus and local contractility of the myometrium may not be reflected by intrauterine pressure changes.[4] At different times of the day and under different physiologic situations, we have noticed that in the pregnant monkey there may also be differences in the amount of intrauterine pressure change generated by individual electromyogram complexes of similar amplitude and duration, but we have not made a detailed study of this relationship. This relationship will be affected by factors that affect activation-contraction coupling such as the density of gap junctions.[16]

The power spectrum showed the majority of activity at low frequency when only contractures were present. The exact frequency peaks depend both on the envelope of duration of the individual contracture and their frequency of occurrence. When the raw data showed mostly contractures, 65% of the power was at frequencies <1 cycle every 9 minutes. When contractions predominated, 84% of the power was at frequencies >1 cycle every 5 minutes. Therefore for future analysis of waveforms from any sensors of myometrial activity we have chosen two windows: <1 cycle every 9 minutes to represent contracture activity and >1 cycle every 5 minutes for contraction patterns.

Quantification of myometrial activity is important if changes throughout gestation and responses to individual pharmacologic agents are to be assessed. The

power spectrum may be precisely quantified by analyzing the power within any spectral frequency range. Thus this method retains both frequency and amplitude characteristics. Analysis of area under either the intrauterine pressure or electromyogram activity envelope provides incomplete information since a given amount of area under curve could reflect periods of either predominantly contraction or contracture activity. Power spectrum analysis also enables information from many hours of recording to be condensed into an easily visible and quantifiable format.

Power spectrum may be used to compare myometrial activity of the same animal between different periods of time, such as the hours of daylight and the hours of darkness. In addition, direct comparison of the same period (e.g., daytime before, during, and after administration of drugs) can be made. Thus when indomethacin was infused into the maternal aorta, contractions were converted to contractures; the main spectral power shifted to the low frequency. This effect was reversed when the indomethacin infusion was stopped.

Power spectrum analysis can also be used to demonstrate whether changes occur at the same time of the day but at different periods of gestation or over successive days of an experimental protocol. For example, in our food withdrawal studies, the power spectral shift from the contractures spectrum to the contractions spectrum was much more marked at nighttime. To study physiologic and pathophysiologic regulation of myometrial activity (e.g., preterm labor), we suggest that computer-based power spectral analysis of features of myometrial activity be applied to the critical times of the day at which a power spectral shift occurs from the contracture to contractions spectrum. In the search for better methods to understand myometrial activity both in experimental animals and in pregnant women, we propose that power spectral analysis will prove to be a powerful tool in the determination of specific patterns of myometrial activity and in the assessment of which patterns are innocuous and which are ominous.

We thank Karen Moore for assistance with the manuscript and Ellen Wolfe and Larry Kantrowitz for their day-to-day attention to the care of the animals. We thank Dr. Robin Gleed for his skilled assistance with the critical anesthesia required for these surgeries.

Pattern of human chorionic gonadotropin binding in the polycystic ovary

James Brawer, PhD,[a] Martine Richard, MSc,[b,] * and Riaz Farookhi, PhD[c]
Montreal, Quebec, Canada

The histologic evolution of polycystic ovaries in the estradiol valerate–treated rat coincides with the development of a unique plasma pattern of luteinizing hormone. To assess the role of luteinizing hormone in polycystic ovaries, it is necessary to evaluate the luteinizing hormone sensitivity of the specific tissues in the polycystic ovary. Therefore, we examined the pattern of luteinizing hormone binding sites in polycystic ovaries. Rats at 4 or 8 weeks after estradiol valerate treatment each received an intrajugular injection of iodine 125–labeled human chorionic gonadotropin. Some rats also received a 1000-fold excess of unlabeled human chorionic gonadotropin in the same injection. Ovaries were prepared for autoradiography. Dense accumulations of grains occurred over the theca of normal and atretic secondary follicles in all ovaries and over clusters of secondary interstitial cells. The iodine label was variable over the typically hypertrophied theca of precystic follicles. The theca of definitive cysts showed little or no label. These results indicate that cyst formation coincides with the loss of luteinizing hormone/human chorionic gonadotropin binding to the affected follicles. (Am J Obstet Gynecol 1989;161:474-80.)

Key words: Follicular cysts, polycystic ovaries, theca, LH/hCG binding

An injection of estradiol valerate produces a polycystic ovarian condition in the rat.[1-3] The ovaries contain large cystic follicles that exhibit characteristic features such as a highly attenuated granulosa cell layer and marked thecal hypertrophy. Numerous clusters of large lipid-filled secondary interstitial cells are scattered throughout the stroma. In addition, the ovaries contain no new corpora lutea and very few normal large secondary follicles.[1-3]

These distinctive morphologic features emerge between 4 and 8 weeks after estradiol valerate treatment. During the first 4 weeks, the ovaries are characterized by numerous large atretic secondary follicles and, in fact, the transition to the cystic state appears to result from an arrest of the atretic process.[3]

The transformation in ovarian morphologic features to the polycystic state coincides with the appearance of a unique pattern of plasma luteinizing hormone (LH).[4] This specific LH pattern is observed in all animals with established polycystic ovaries regardless of the duration of the condition. This suggests that LH plays a significant role in the development and maintenance of the cystic ovary. The ovary contains a variety of structures that are normally responsive to LH. At present we have no information on the LH receptivity of the tissues in the polycystic ovary; therefore we examined the distribution of LH binding sites in the polycystic ovary by means of autoradiography, with iodine 125–labeled human chorionic gonadotropin (hCG) used as a ligand. hCG binds specifically to the LH receptor with an affinity equal to that of LH.[5] It has been used as a probe of the LH receptor for more than a decade. Our results demonstrate that cyst formation coincides with the loss of LH binding in the cells of the theca interna.

Material and methods

Treatment of animals. Six-week-old female Wistar rats were purchased from Charles River (Canada) Ltd. (St. Constant, Quebec). The animals were maintained under conditions of controlled light (12 hours per day) and temperature (22° C) and had free access to food (Purina Rat Chow, Ralston Purina, St. Louis) and water. Estrous cyclicity was monitored by the daily examination of vaginal smears. Only animals that exhibited two consecutive normal 4-day estrous cycles immediately before treatment were used.

A total of 17 animals (34 ovaries) were studied. All animals exhibited persistent vaginal cornification by 2 weeks after estradiol valerate treatment. Each animal was injected intramuscularly with 2 mg estradiol valerate in 0.2 ml sesame oil. Because we had previously shown that true follicular cysts appear between 4 and 8 weeks after estradiol valerate injection,[3] groups of animals were studied only at each of these time points

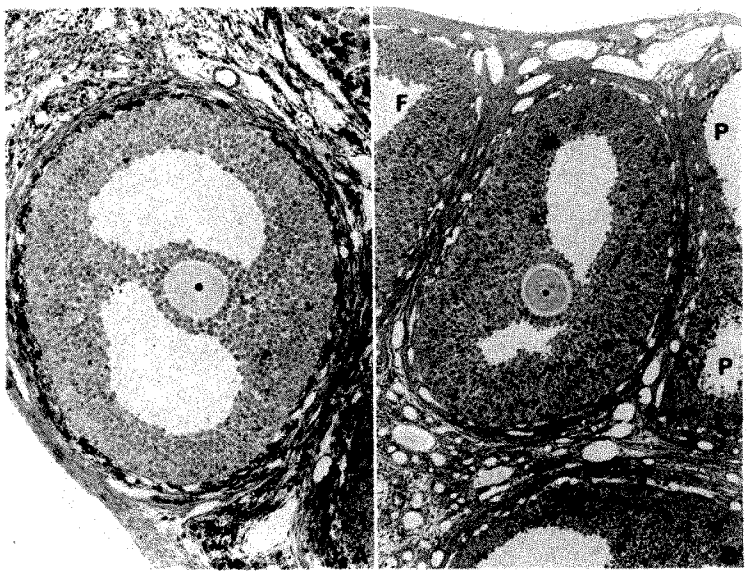

Fig. 1. A, Ovary exposed to ^{125}I-hCG. Theca interna of healthy follicle in center of field is heavily labeled, as are theca and perimural granulosa cell layers of segment of type III large follicular structure in extreme lower right corner of field. (Original magnification ×200.) **B,** Ovary exposed to ^{125}I-hCG and large excess of unlabeled hCG. Healthy follicle appears in center of field with segment of type III large follicular structure *(F)* and portion of precystic follicle *(P)*. Autoradiographic reaction product is absent from all three structures. (Original magnification ×156.)

after estradiol valerate treatment. At 4 weeks after estradiol valerate treatment, two animals each received ^{125}I-hCG (100×10^6 cpm/0.3 ml phosphate-buffered saline solution; specific activity, 50 μCi/μg). Three other animals received the same dose of ^{125}I-hCG and an approximately 1000-fold excess (on a mass basis) of unlabeled hormone. Similarly, at 8 weeks after estradiol valerate treatment, nine animals were injected with labeled hCG alone and three animals received the labeled hormone and a 1000-fold excess of unlabeled hormone. Both ovaries of each of the animals exhibited cystic follicles when studied at 8 weeks. The same was true for the ovaries of the 4-week animals except that there were fewer definitive cysts per ovary.

Hormone injection and perfusion procedure. Animals were anesthetized with 15% urethane injected intraperitoneally (1 ml/100 gm body weight) before injection with hCG. The jugular vein was exposed and the hCG was injected directly therein. Thirty minutes later the animals were perfused. The 30-minute exposure was based on previous reports that maximal ovarian binding of hCG occurs well within this interval.[6, 7]

A ventral incision was then made and the descending aorta and inferior vena cava were exposed. A loose ligature was placed around the two vessels at a level just above the branching of the two renal veins. The aorta was cleared of fat and connective tissue and was clamped at the point of bifurcation of the common iliac arteries. An 18-gauge needle was then introduced into the aorta just above the clamp. The needle was attached to a length of intravenous tubing that branched at the proximal end. Each branch was inserted into a bottle suspended 3 feet above the perfusion table. One bottle contained lactated Ringer's solution and the other a fixative consisting of 1% glutaraldehyde and 1% formaldehyde in 0.2 mol/L phosphate buffer (pH 7.4).

A slow flow of Ringer's solution was started just before insertion of the needle into the aorta; the flow of the lactated Ringer's solution was then increased to its maximum. Simultaneously the aortic ligature was tightened and a small incision was made in the right renal vein. When the right kidney appeared to clear of blood, the perfusate was switched from the lactated Ringer's solution to the fixative. The lactated Ringer's solution and the fixative were both at room temperature. Fixative (100 to 150 ml) was perfused through the system. The ovaries were then removed, cleared of fat and connective tissue, and placed in fixative overnight.

Preparation for autoradiography. Each ovary was cut into four or five pieces. The cuts were made to include grossly invisible follicular structures in the tissue blocks. The tissues were washed in phosphate-buffered dextrose and were postfixed for 2 hours at 4° C in a solution of 2% osmium tetroxide and 2% potassium ferrocyanide.[8] The tissues were then washed twice in a 2.4% sodium chloride solution, dehydrated in a graded methanol series, and embedded in Epon.[9] The Epon blocks were trimmed and 1 μm thick sections

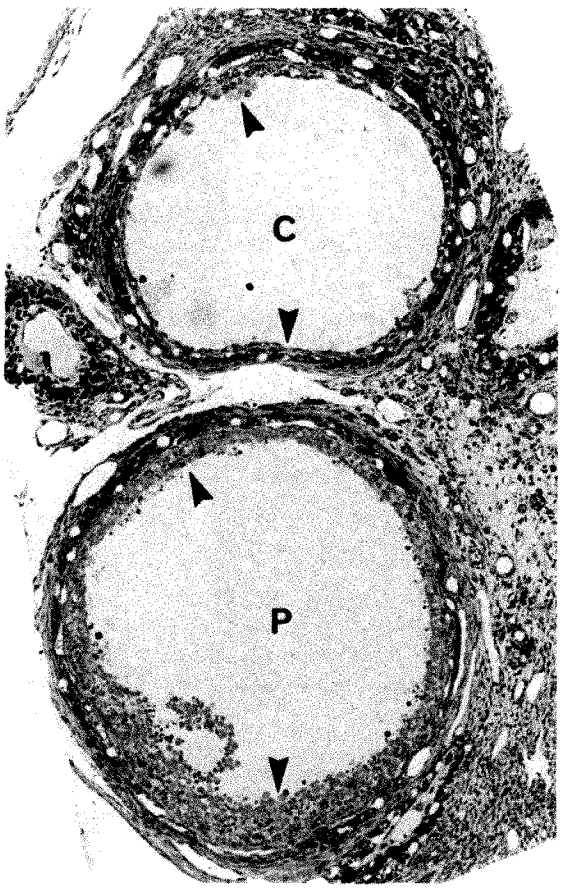

Fig. 2. Cystic and precystic follicles. Precystic follicle in lower half of field *(P)* exhibits several severely atretic layers of granulosa cells *(arrowheads)* in contrast to cystic follicle *(C)* that contains a relatively uniform single layer of granulosa cells *(arrowheads).* (×135.)

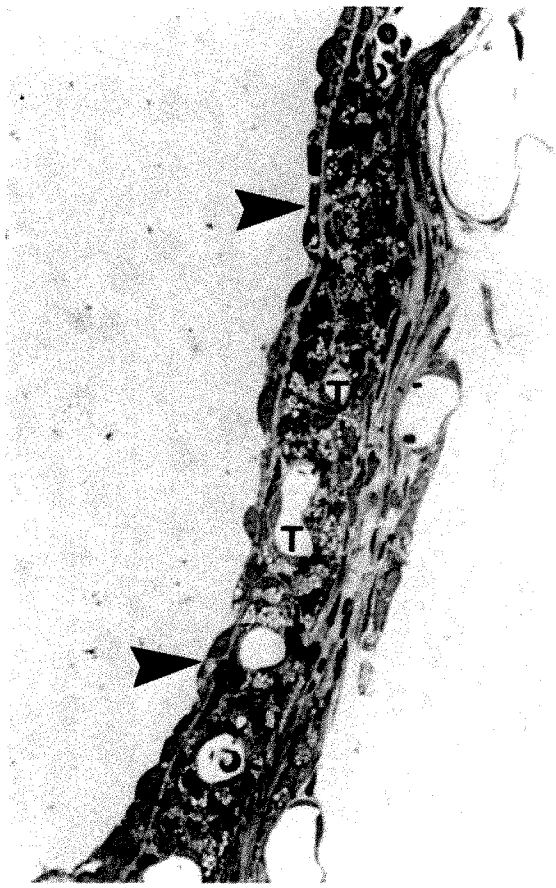

Fig. 3. Cyst wall in ovary exposed to ^{125}I-hCG. Large polygonal cells make up theca interna *(T).* Lipid droplets appear as numerous clear vesicles in thecal cells. Granulosa layer *(arrowheads)* is one cell thick. Note absence of autoradiographic label. (×625.)

were cut with glass knives on a Reichert microtome. All sections were cut within 2 weeks of perfusion.

Slides containing the sections were prewarmed, flooded with 5% ferric ammonium sulfate for 5 minutes (while on the hot plate), and rinsed in distilled water. They were then flooded with Regaud's hematoxylin for 1 minute, washed, and dried.

Autoradiography. Autoradiography of the stained sections was done according to the procedure of Kopriwa and Leblond.[10] The slides were dipped in undiluted Kodak NTB 2 emulsion and were then air-dried for 1 hour in complete darkness. The coated slides were placed in sealed black plastic boxes that contined anhydrous calcium sulfate (desiccant) and stored at 4° C. A test slide removed at 8 days of exposure revealed significant autoradiographic reaction. Therefore most of the slides were removed and developed at this time. A few slides from each ovary were exposed for 21 days. Slides were submerged for 6 minutes in freshly prepared Kodak D-170 developer at 18° C, rinsed in distilled water, fixed in 24% sodium thiosulfate, washed, and air-dried; a coverslip was applied. Photomicrography was done on a Leitz Laborlux D microscope with a Wild photoautomat MPS 45 camera attachment.

Chemicals and reagents. Estradiol valerate (Delestrogen, Squibb Canada, Inc.) was purchased from the Royal Victoria Hospital, Montreal. Highly purified hCG (CR-121; 13,450 IU/mg) was a gift from the Center for Population Research of the National Institute of Child Health and Human Development, Bethesda. Iodination and characterization of iodinated hormone were done in our laboratories in accordance with the method of Ireland and Richards.[11] hCG (1000 IU/mg) used as excess unlabeled hormone in controls was obtained from Ayerst Laboratories (Montreal).

Results

The morphologic features of the precystic and cystic ovaries in the estradiol valerate–treated rat have been described previously.[3, 12] Although the ovaries observed in this study generally conform to those descriptions, the use of perfusion fixation and Epon embedding has

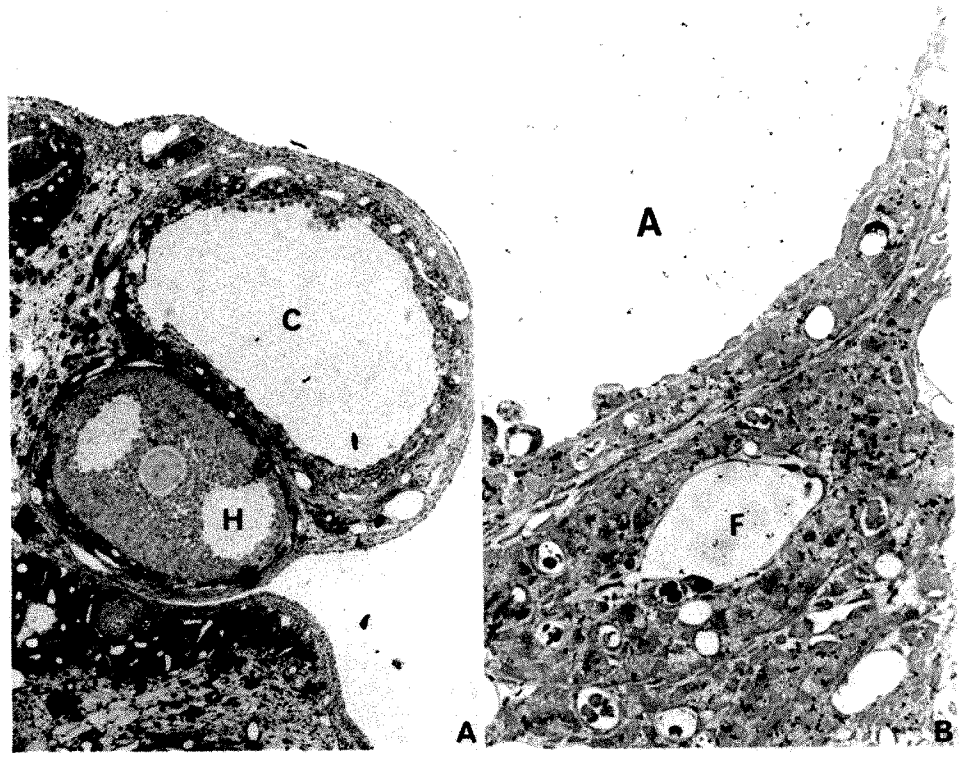

Fig. 4. A, Healthy and cystic follicles in ovary exposed to ^{125}I-hCG. Theca interna of healthy follicle *(H)* is heavily labeled in contrast to that of cyst *(C)*. (Original magnification ×125.) **B,** Wall of cystic follicle in ovary exposed to ^{125}I-hCG. Portion of antrum *(A)* appears in upper left of field. Very old atretic follicle *(F)* is just beneath segment of cyst wall. Large lipid-filled thecal cells in this segment of cyst wall exhibit few grains. (Original magnification ×500.)

permitted a more detailed histologic examination and has revealed several novel features. The specificity of ^{125}I-hCG binding can be appreciated by examining sections from animals injected with labeled hormone to comparable sections from animals that received labeled hormone and a large excess of unlabeled hormone (Fig. 1). The ovaries of all controls that received an excess of unlabeled hormone exhibited negligible autoradiographic labeling.

In this study we observed three classes of large follicular structures, none of which appear in the normal ovary. The first of these structures exhibited thecal hypertrophy and a size that approximated that of the true cyst (Fig. 2). However, the antrum was encompassed by several irregular layers of degenerate granulosa cells. This large follicular structure is identical to the precystic follicle described previously.[3] ^{125}I-hCG binding in these follicles was scant and limited to the theca.

The second type of large follicular structure, the typical follicular cyst, consisted of a large antrum surrounded by one or two layers of granulosa cells and a hypertrophied thecal cell layer (Fig. 2). The thecal cells were often polygonal in shape and very large in contrast to the small fusiform thecal cells observed in healthy secondary follicles. The large thecal cells in cystic follicles frequently contained numerous lipid droplets (Fig. 3). However, in some cysts the theca also contained small fusiform cells. Labeled hCG binding in these follicles was absent in the granulosa and rare to absent in the theca (Figs. 3 and 4).

The third type (type III) of large follicular structure exhibited a unique appearance (Fig. 5). It was the largest of the follicular structures and consisted of four or five layers of healthy granulosa cells surrounding a huge antrum. The granulosa cells, however, differed from those in a normal secondary follicle; they were smaller, more densely stained, more densely packed, and more variable in shape. These differences can best be seen in Fig. 6. Mitotic figures were also occasionally seen randomly scattered throughout the granulosa cell layers. The thecal cell layer was of ordinary thickness and consisted of the small fusiform cells that typify the healthy secondary follicle. Both the theca and granulosa cell layers of these follicles displayed labeled hCG binding. Thecal labeling was intense; dense patches of labeling occurred over the perimural granulosa (Fig. 6).

The precystic follicle was the most commonly observed large follicular structure 4 weeks after estradiol valerate treatment. Definitive cysts were rare and the

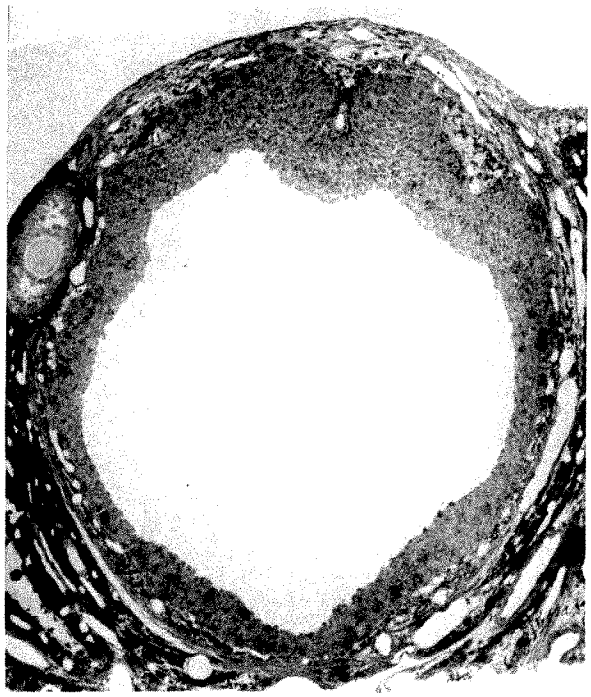

Fig. 5. Type III large follicular structure. This type of follicular structure is the largest seen in polycystic ovary. It is characterized by healthy granulosa cell layers and by modest theca interna consisting of several layers of small fusiform cells. (Original magnification ×140.)

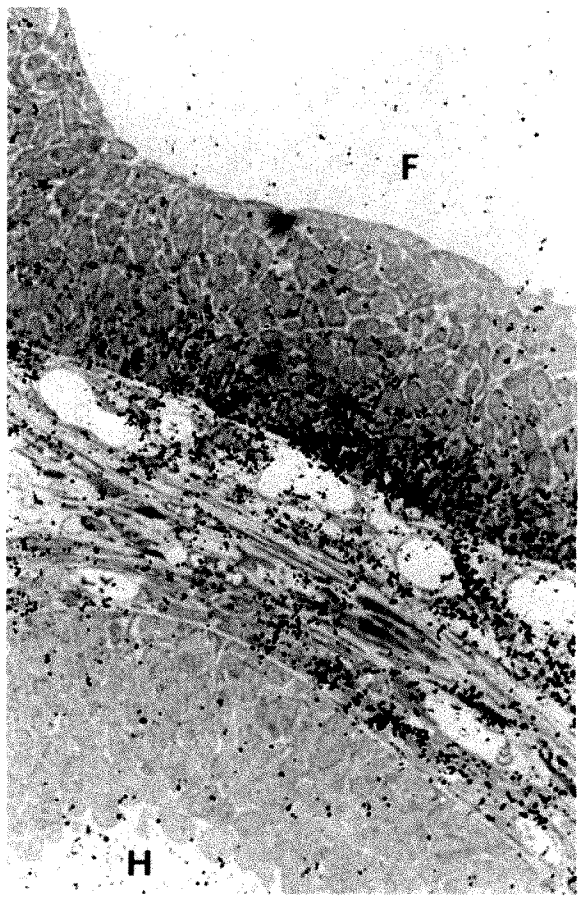

Fig. 6. Segments of type III large follicular structure *(F)* and of healthy follicle *(H)* in ovary exposed to ^{125}I-hCG. Both theca and perimural granulosa cell layers of type III large follicular structure are heavily labeled. Only theca interna is labeled in segment of healthy follicle. (×500.)

type III large follicular structure was never seen. By 8 weeks the precystic follicle was still the most commonly observed large follicular structure, although numerous cysts were also present. The type III large follicular structure also appeared at 8 weeks but occurred approximately half as frequently as the definitive cysts.

There was considerable histologic variation in the multitude of atretic secondary follicles, not only in the granulosa cell layers but also in the theca. For example, the proportion of large vacuolated polygonal thecal cells to the small fusiform variety differed considerably between follicles. Generally, the more severely atretic follicles had the greater proportion of large polygonal cells. Severely atretic follicles in various states of collapse contained exclusively large heavily vacuolated thecal cells that were indistinguishable from secondary interstitial cells. All normal and atretic secondary follicles that were observed exhibited label over the theca. Even severely atretic follicles, in which the granulosa cell layer had been lost and which were in a state of near collapse, exhibited intense thecal labeling (Fig. 7).

Clusters of secondary interstitial cells were numerous throughout the stroma. Apparently healthy primary and small secondary follicles also occurred. Healthy secondary follicles were more numerous at the 4-week posttreatment interval than at 8 weeks. The numerous clusters of secondary interstitial cells were variably labeled. The most recent clusters, in which remnants of the antecedent follicular structure were still visible (e.g., a collapsed antrum), were heavily labeled. However, more irregular clusters of secondary interstitial cells were labeled to a lesser extent and the label was not uniformly distributed over all cells. Some patches of interstitial cells showed little or no label. These were randomly interspersed among intensely labeled clusters.

Comment

Three unusual large follicular structures were observed in the polycystic ovary in this study. Two of these, the cyst and the precystic follicle, had been identified and described previously.[3] To our knowledge, the third variety has not been described. This large follicular structure exhibits a normal theca and several healthy layers of granulosa cells typical of a large preovulatory follicle. Moreover, the presence of dense hCG binding in the perimural granulosa cells also indicates an active preovulatory follicle.[13] However, the total absence of corpora lutea in all ovaries examined, both at 4 and 8 weeks, precludes the possibility that these large

follicles are ovulating. However, they may be capable of ovulation if exposed to an LH surge of sufficient magnitude, an event that under ordinary circumstances would not occur in the rat with polycystic ovaries. We have demonstrated, however, the presence of corpora lutea in the previously polycystic ovary after an LH surge induced by luteinizing hormone–releasing hormone.[12] The most likely antecedent to such corpora lutea would seem to be the type III large follicular structure. However, their remarkable size and the presence of mitotic figures in the mural granulosa cell layers further distinguish these unique structures from ordinary preovulatory follicles. At present, we are unable to explain how and why such structures develop in a milieu in which most follicles become atretic or cystic. The fate of these structures is also unclear at present.

We have previously shown that cystic follicles are not merely preovulatory follicles, but unique follicular structures without counterpart in the normal ovary.[3] The added resolution afforded by perfusion fixation and Epon embedding in this study confirms this finding.

The most significant finding in our study is the paucity of hCG binding to the theca of true cystic follicles. This is in marked contrast to thecal binding in normal and atretic follicles within the same ovary. Indeed, the hCG binding over noncystic theca and secondary interstitial cells was often so intense that individual grains could not be assigned to cells of origin, and cell boundaries could not be accurately determined in the underlying tissue. This rendered grain counting unfeasible and unnecessary because so very few grains occurred over the theca of cystic follicles.

Thus it appears that the arrest of atresia and the transition from the precystic to the cystic condition coincide with a loss in hCG binding and, presumably, a loss in sensitivity to LH. Why this occurs only in selected follicles is unclear. Furthermore, this observation is particularly puzzling in view of the elevated androgen concentrations that have been reported in cyst fluid in human polycystic ovaries.[14-16] We have not measured androgen concentrations in the cysts of estradiol valerate–treated rats (the fluid yield is exceedingly small). However, plasma androgen (testosterone, androstenedione, or dehydroepiandrosterone) concentrations in these animals are similar to those of normally cycling controls.[12] Although it is conceivable that thecal androgen production in cysts may be regulated by a factor other than LH, it appears more likely that much of the androgen production in the polycystic ovary may be explained by the extensive LH-sensitive secondary interstitial tissue,[17] and the LH responsive thecal tissue of noncystic large follicular structures.

In addition to the large follicular structures unique to the polycystic ovary, a variety of ordinary structures commonly encountered in normal ovaries was observed. These include normal and atretic primary and secondary follicles and clusters of secondary interstitial cells in the stroma. Moreover, the pattern of hCG binding to these structures was identical to that reported previously in normal ovaries and in ovaries in which atresia was experimentally induced. It has been shown, for example, that binding of hCG to granulosa cells occurs only in large normal secondary follicles.[18, 19] The hCG binding to granulosa cells of large atretic follicles is very limited.[20-23] Differences in the level of hCG binding to granulosa cells, in these models is inversely proportional to the degree of atresia.

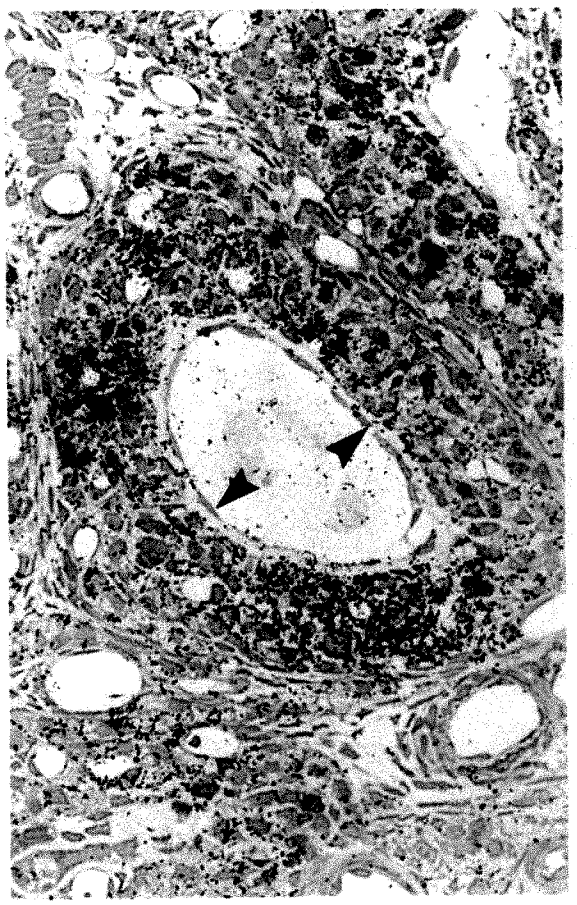

Fig. 7. Follicle in terminal stage of atresia in ovary exposed to ^{125}I-hCG. Thick ellipsoidal theca interna, consisting of hypertrophied lipid-filled polygonal cells, is heavily labeled. Lumen, lined by single layer of granulosa cells *(arrowsheads)*, is near point of collapse. (×500.)

Binding of ^{125}I-hCG to the theca interna of atretic follicles was either greater than[19] or equivalent to[23] that of healthy follicles of similar size. Similarly, the secondary interstitial cells in these models of atresia showed variable binding. As in our study, the most recently formed interstitial clusters exhibited the most intense label.[19]

Thus the histologic components common to both the polycystic and noncystic ovary display similar hCG binding irrespective of the type of ovary in which they

occur. This underscores the fact that not only is the cystic follicle histologically unique but also it exhibits LH binding characteristics unlike that of any other follicular structure.

The results of our study raise a number of important questions. It is not clear whether the loss of thecal LH binding is causal to the transition between the precystic and the cystic state, or whether it is a consequence of cyst formation. Moreover, we are confronted with an unexpected situation in which hypertrophied, lipid-containing thecal cells are apparently insensitive to LH. Paradoxically, thecal cells of identical appearance in atretic follicles and in interstitial cell clusters within the same ovary exhibit intense hCG binding. The functional properties, steroidogenic capabilities, and the roles played by these different thecal populations in polycystic ovaries remain to be determined.

We thank Dr. Beatrix Kopriwa and Mr. Fernando Evaristo for technical assistance and advice in autoradiography.

Effect of a 48-hour intravenous Δ^4-androstenedione infusion on the pregnant rhesus monkey in the last third of gestation: Changes in maternal plasma estradiol concentrations and myometrial contractility

Jorge P. Figueroa, MD, PhD, M. Barbera O. M. Honnebier, MD, Zbigniew Binienda, DVM, Jeffrey Wimsatt, DVM, and Peter W. Nathanielsz, MD, PhD

Ithaca, New York

Increased myometrial activity in the pregnant rhesus monkey occurs in situations in which plasma estrogen concentrations are elevated. Examples of such situations are after laparotomy, with or without hysterotomy, and before delivery. The increased activity occurs primarily in the hours of darkness. To investigate the possibility of a causal relationship between the rise in estrogens and myometrial activity, we infused androstenedione intravenously for 48 hours to the rhesus monkey in the last third of gestation. Myometrial activity was quantified either as an increase in the number of individual contraction events or as a change in the power spectrum at high frequencies characteristic of contractions. Androstenedione infusion was followed by increased myometrial activity. Maternal plasma 17β-estradiol concentration was significantly elevated at 10 AM on the second day of androstenedione infusion. We conclude that, in the rhesus monkey late in gestation, estradiol may play a role in the regulation of the contraction activity observed during the hours of darkness in several different situations. (AM J OBSTET GYNECOL 1989;161:481-6.)

Key words: Estrogens, estrogen precursors, myometrial contractility in pregnancy

Maternal plasma estrogen concentrations in the pregnant rhesus monkey are high throughout gestation and rise at delivery.[1] This increase is not as dramatic as that described in the pregnant sheep.[2] In the nonpregnant sheep, estradiol administration results in both stimulatory and inhibitory effects on the myometrium.[3] However, the role of estrogens in stimulating myometrial activity during pregnancy in the primate has not been studied in detail.

In the pregnant rhesus monkey, 24-hour patterns of maternal plasma steroid hormone concentrations have been demonstrated.[4] Because of possible delays in the passage of estradiol formed in the placenta and membranes in reaching maternal blood plasma,[5] it is difficult to assess the potential for a causal relationship of changes in plasma estradiol concentration and the well-established patterns of myometrial activity that have been described by several investigators.[6, 7] Myometrial activity in the relatively unstressed instrumented pregnant rhesus monkey is generally of the contracture type when recorded either with electromyogram leads or intrauterine pressure measurement.[7] This is true unless the mother has recently undergone surgery, is stressed in some other fashion, or is about to deliver. In each of these situations contractures change to predominantly contractions around the hours of darkness.[7, 8] We have demonstrated that the administration of the aromatase inhibitor 4-hydroxyandrostenedione will inhibit the change to contractions that is normally observed after laparotomy and hysterotomy.[9] The possible causal relationship linking changes in hormone concentrations to the increase in nocturnal contraction activity that has been demonstrated after surgery,[7] during certain forms of stress, such as food withdrawal,[8] and before labor and delivery[7] remains to be determined.

Short-term administration of androstenedione to either the fetus or mother[10] results in increased plasma concentration of estradiol in pregnant monkeys. Estrogens will cross the primate placenta.[11] In this study we administered Δ^4-androstenedione for 48 hours to increase placental estrogen production in the pregnant rhesus monkey. We wished to determine whether maintained elevation of maternal plasma estrogen concentrations would be accompanied by a change from myometrial contractures to contractions around the hours of darkness.

Material and methods

Care of animals

Surgical procedures. Five pregnant rhesus monkeys of known gestational ages were obtained from the California Regional Primate Center in Davis, Calif., and acclimated to the laboratory conditions as previously described.[7, 8] The animals were housed in rooms with controlled light cycles (14 hours light and 10 hours dark) (Fig. 1), with lights on at 6 AM. Food provided was Purina 5045 Monkey Chow (Purina, St. Louis) and fresh fruits. Water was provided as desired during the experimental period. Animals were instrumented using techniques described previously.[7, 8] Briefly, catheters were placed in the maternal femoral artery and vein with the animal under halothane anesthesia. In each animal, two pairs of myometrial electromyogram leads were placed on the anterior wall of the uterus. Two catheters made of Tygon microbore tubing (Norton Performance Plastics, Akron, Ohio; inner diameter 1.27 mm, outer diameter 2.29 mm) with a side hole 1 cm from the tip were placed with 3 to 6 cm of the catheter within the amniotic cavity. A small retaining collar of Tygon prefabricated around the catheter was located just within the uterus. At surgery monkeys ranged from 92 to 107 days' gestational age.

Recording of intrauterine pressure and myometrial electromyogram and data storage. The uterine electromyogram was recorded from multistranded bipolar stainless steel wires (Cooner AS 632, Chatsworth, Calif.) implanted 3 to 5 mm apart on at least two sites of the myometrium.[7, 8] One of the intraamniotic catheters was connected to a pressure transducer (Cobe, Lakewood, Colo.) that was placed in a small box on the monkey's back, beneath the jacket. Acquisition of the myometrial electromyogram and intrauterine pressure waveforms was performed with a custom-built computer-based data acquisition system. Details of sampling frequency and filters have been previously published.[12] Briefly, the signals (electromyogram and intrauterine pressure) were sampled at 32 Hz, and the average value over 8 seconds was digitized and stored on tape with a time signal. The initial sampling frequency of 32 Hz prevented aliasing problems with changing signals, whereas the lower storage rate of one reading every 8 seconds creates a manageable volume of data for subsequent analysis.

Data analysis. Fast Fourier Transform and power spectrum analysis were performed on the digitized intrauterine pressure and electromyogram data with the Asyst 2.0 system. Since the Fast Fourier Transform[13] software program works on multiples of 4096 data points, we analyzed only the hours 10:54 AM to 8 PM for periods of light and 8 PM to 5:06 AM for the periods of darkness. Integration of the area under the curve of the power spectrum was performed by addition of all the data points: for low frequencies 0.01 to 0.11 cycle/min or less than one cycle every 9 minutes, and for high frequencies 0.2 to 0.8 cycle/min or greater than one cycle every 5 minutes.[14]

Individual epochs of activity were calculated with a minimum duration of 16 seconds as a requirement, a 2-hour running mean as threshold, and a 40-second delimiter to establish the termination of an event. Contractions were classified in a 16- to 96-second window, and contractures were classified in a 96- to 896-second window, with techniques similar to those we have reported in sheep.[12]

Administration of Δ^4 androstenedione in intralipid. Forty-eight milligrams of Δ^4-androstenedione (Sigma Chemical, St. Louis) was prepared daily and mixed with 6 ml of a 10% fat emulsion (intralipid 10%, Kabi Vitrum, Inc., Alameda, Calif.). In the four animals in the Δ^4-androstenedione group this emulsion was infused for 48 hours at a rate of 0.25 ml/hr with a C-99 battery-operated pump (Razel Scientific, Stamford, Conn.). Intralipid alone was infused as a control in three animals.

In two animals the intralipid study was performed 1 week before the androstenedione infusion.

Blood sampling. Maternal arterial blood samples were taken into sterile, cold, heparinized syringes, placed in ice-cold heparinized tubes, and immediately cooled in ice. Blood was centrifuged at 4° C for 3 minutes at 6000 rpm. Plasma was removed at once with sterile pipette and was flash-frozen in liquid nitrogen. All samples were stored at −20° C. The red cells were resuspended in a volume of saline solution equal to the volume of plasma and reinjected into the maternal arterial catheter. Samples were taken at 9 PM, 10 AM, and 3 PM.

Statistical analysis. Plasma estradiol data were analyzed by paired *t* test comparing data obtained on the second control day versus the second experimental day at each individual sampling time in both the androstenedione- and intralipid-infused groups. Uterine electromyogram activity was analyzed by use of the previously described output of the computerized power spectrum analysis and the epoch counting analysis. Total area under the curve data for the power spectrum windows was normalized for amplitude with the value for each animal on control day 2 considered 100%. The paired *t* test was used to compare myometrial activity on the second control day and the second experimental day in both the androstenedione- and intralipid-infused groups.

Radioimmunoassay of estradiol. Maternal plasma estradiol concentration was measured in duplicate aliquots of 200 μl of plasma after ether extraction. The Coat-a-Count antibody-coated tube with the iodine 125-labeled estradiol kit (TKE 25, Diagnostic Products Corp., Los Angeles) was used. Specificity was further evaluated by comparing values obtained after ether extraction of nine individual pregnant monkey plasma samples followed by column chromatography on Sephadex LH 20 (Pharmacia Fine Chemicals, Piscataway, N.J.) with values for the same sample extracted but not chromatographed. Chromatographed samples had values that were 98.0% ± 15.9% (mean ± SD, $n = 9$) of the estradiol concentration obtained on the same sample without chromatography. Parallelism was confirmed by assaying serial dilutions of normal rhesus monkey pregnancy plasma and nonpregnant rhesus monkey plasma to which estradiol had been added.

Results

Table I shows the changes in maternal plasma 17β-estradiol concentration in the three daily samples on the second day of the control period, on the second day of the androstenedione infusion period, and the second day of the recovery period in four monkeys infused with androstenedione in intralipid, and in three control animals infused with intralipid alone. On the second day of the androstenedione infusion period, maternal plasma estrogen concentration was elevated at all three sampling times. This increase was statistically significant compared with the same times of the second control day, respectively ($p < 0.05$). Although only the 9 PM samples were available from all three control animals, estradiol concentrations at this time showed no rise from the values on the control day 2.

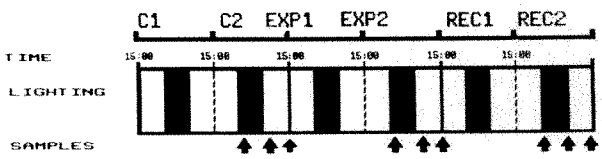

Fig. 1. Time line for the 6 days of the experiment. All animals were infused with saline solution on the two control days, *C1* and *C2*. On the experimental days, *EXP1* and *EXP2*, animals were infused with either androstenedione (2 mg/hr) in intralipid or intralipid alone. Blood samples were taken on the second control day *(C2)*, experimental day two *(EXP2)*, and the second day of recovery *(REC2)*.

Myometrial electromyogram recordings

Effect of androstenedione on myometrial contractility. Fig. 2A shows the effect of two days of intravenous androstenedione infusion on the power spectrum of myometrial electromyogram during the hours of darkness in one pregnant rhesus monkey. By the second night of infusion, maternal plasma estradiol was elevated and the concentration portion of the power spectrum was increased. In contrast, there was no change in the power spectrum at any time when the intralipid vehicle was infused alone (Fig. 2B).

Fig. 3, *A* and *B*, shows the changes that occur in the power spectrum areas in the contractures and contractions windows in the hours of light and darkness during the androstenedione and intralipid infusions, respectively. During the hours of darkness, there was an increase in contraction type activity. Similarly, when the individual epochs of activity were separated into contractures (96 to 896 seconds' duration) and contractions (16 to 96 seconds' duration) throughout the 3 days when analysis was conducted, there was a significant increase in contraction frequency on the second night of androstenedione infusion ($p < 0.05$) (Fig. 4, *A*).

Comment

The continuous intravenous administration of androstenedione for 48 hours to the pregnant rhesus monkey resulted in a significant, maintained rise in maternal plasma estradiol concentration. This observation confirms the findings of others using 4-hour infusion that, in the nonhuman primate, intravenously administered C19 androgen precursors can be converted to estrogens late in pregnancy.[10] In this study, estrogen concentrations rose to levels slightly higher than those previously described as being present at

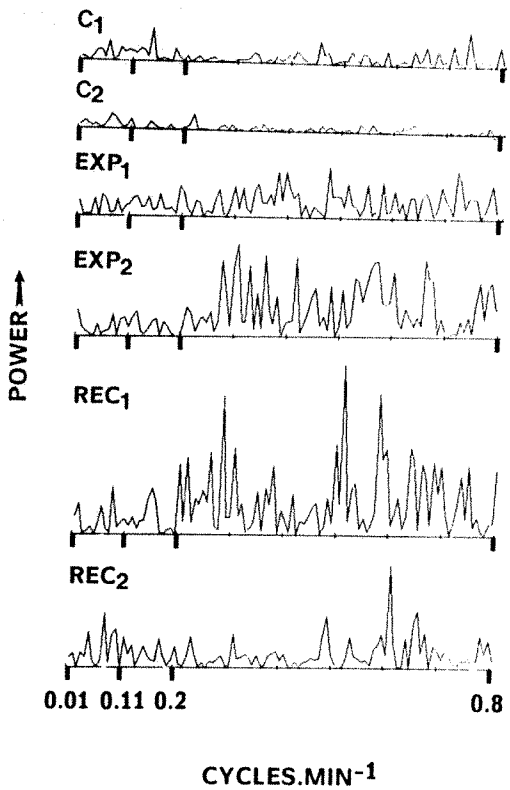

Fig. 2A. Effect of androstenedione infusion (2 mg/hr in intralipid 10% at 0.25 ml/hr) intravenously to a pregnant rhesus monkey on myometrial electromyogram power spectrum during the hours of darkness; control days 1 and 2 (C_1 and C_2) followed by 2 days of androstenedione (EXP_1, EXP_2); followed by 2 days of recovery (REC_1, REC_2).

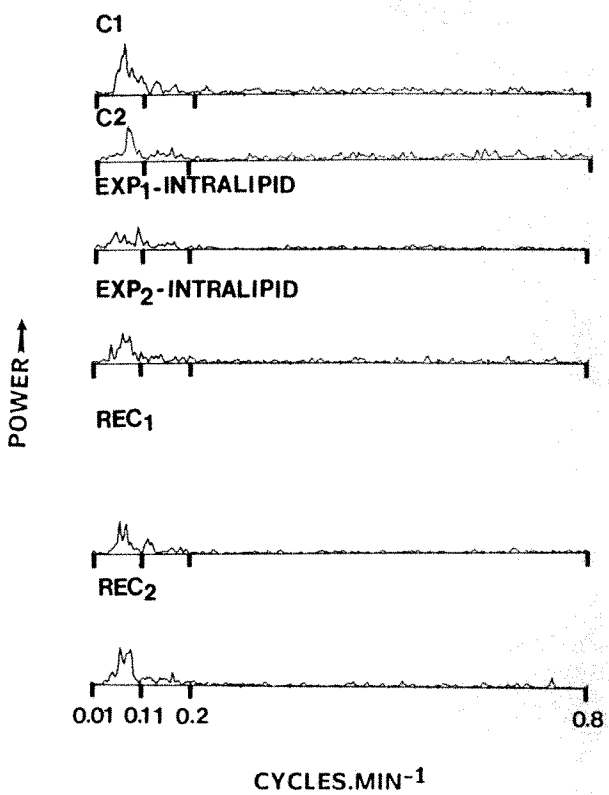

Fig. 2B. Effect of intralipid 10% infusion (0.25 ml/hr) on myometrial electromyogram power spectrum during the hours of darkness; days *C1*, *C2* correspond to the 2 control days of the androstenedione infusion; EXP_1 and EXP_2 were the days of intralipid infusion; REC_1 and REC_2 were equivalent to the recovery days of androstenedione infusion.

term in the pregnant rhesus monkey.[1] This elevation in plasma estrogen concentrations was accompanied by a statistically significant increase in the incidence of nocturnal contractions. Although intrauterine pressure was also recorded in our study, we have not examined intrauterine pressure data statistically since movement artifacts in the free-ranging, tethered animal may compromise analysis. These concerns are probably of lesser importance when studies are conducted with the primate in a restraining chair.

In the pregnant sheep the stress of food withdrawal late in pregnancy also increases myometrial activity and may lead to preterm labor.[15] Maternal plasma estrogen concentrations are increased in this situation.[16] We have previously demonstrated that 48 hours of food withdrawal in the pregnant rhesus monkey in the last third of gestation also leads to an increase in contraction-type myometrial activity.[8] During the same study an increase in maternal estradiol was noted.[17] Because of the presence of a fetoplacental unit the locations of the biochemical pathways leading to estrogen production in the nonhuman primate are not directly comparable to those in the sheep.[10] Estrogen has been shown to play a role in progesterone production in the baboon[18]; thus the possible interplay of these steroids complicates the picture.

Suppression of maternal and fetal adrenal function by adminstration of dexamethasone to the pregnant monkey not only depresses myometrial activity, but also abolishes the 24-hour rhythm observed in myometrial activity.[19] This depressant effect may well be due to inhibition of estrogen production. However, other mechanisms are likely to play a role because mean uterine activity returned to baseline levels in the 48 hours after dexamethasone treatment, but the peak in nocturnal activity remained absent.[19]

Dexamethasone has been shown to prevent the normal increase in maternal plasma estrogens that occurs in the pregnant rhesus monkey at term. Administration of dexamethasone was accompanied by a prolongation of gestation.[19] In contrast, estradiol administration failed to produce preterm delivery in the presence of a live fetus.[20] However, amniotic implants of estradiol will result in preterm delivery in the rhesus monkey, suggesting that the site of generation or administration of estrogen may be critical.[20] Partly because of these

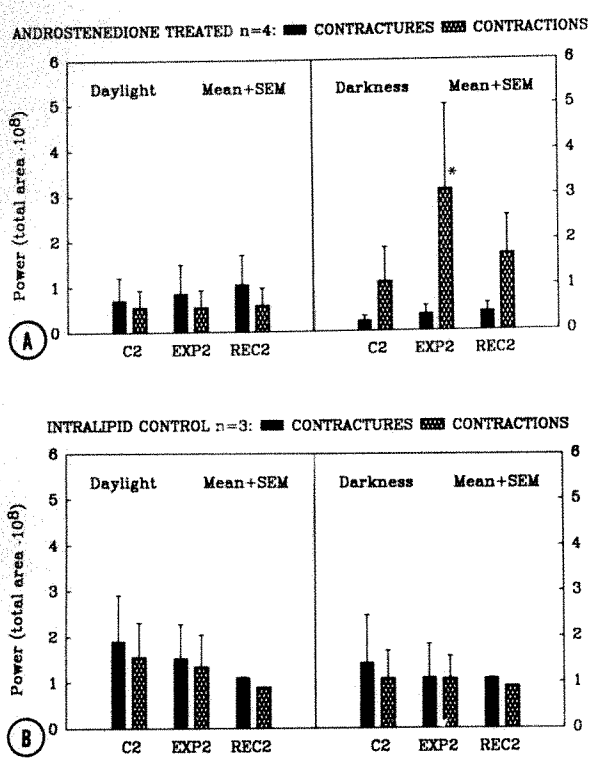

Fig. 3. Effect of 48-hour infusions of intravascular androstenedione **(A)** and intralipid **(B)** to the pregnant rhesus monkey. Two power spectrum windows were analyzed. Contractures (■) were represented in the 0.01 to 0.11 cycles/min window; contractions (▩) were represented in the 0.2 to 0.8 cycles/min window. No changes occurred in either window during the hours of light (10:54 AM to 8 PM). During the hours of darkness (8 PM to 5:06 AM) the power in both the contractions and contractures window was significantly increased on the second day of androstenedione infusion ($p < 0.05$). Mean ± SEM; $n = 4$ for androstenedione infusion and $n = 3$ for intralipid controls. *C2* is the second control day; *EXP2* is the second day of either intralipid or androstenedione infusion. *REC2* is the second recovery day of the 6-day protocol. *Asterisk*, $p < 0.05$ when *EXP2* was compared with *C2*. Intralipid 10% or androstenedione 2 mg/hr in 10% intralipid infused on the 2 experimental days.

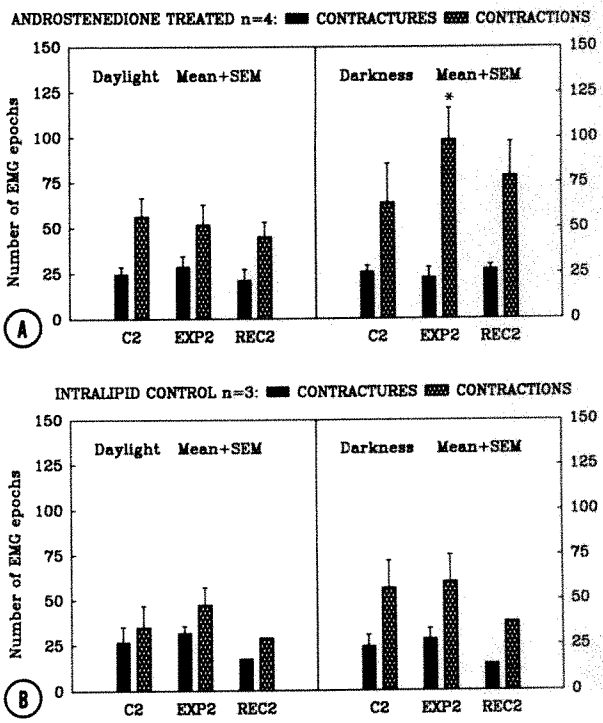

Fig. 4. Effect of intravascular androstenedione **(A)** and intralipid **(B)** infusions to the pregnant rhesus monkey for 48 hours on the number of myometrial contraction and contracture type epochs. Contractions (▩) represent epochs lasting 16 to 96 seconds and contractures (■) epochs lasting 96 to 896 seconds. The only significant change was the increase in contraction frequency on the second night of androstenedione infusion ($p < 0.05$). Hours of daylight analyzed from 10:54 AM to 8 PM; hours of darkness were 8 PM to 5:06 AM.

observations we chose to infuse androstenedione as an estrogen precursor to stimulate estrogen production at its normal site rather than infuse estradiol directly.

The change from contractures to labor contractions that occurs at term in many species is accompanied by changes in absolute maternal plasma estrogen levels or the estrogen/progesterone ratio.[1,2] The most likely explanation of our data is that estrogen production at the normal site from precursors administered intravenously can modify myometrial activity. A consistent feature of postsurgical stress, food withdrawal,[8] and the current study is the observation that in the presence of continuous stress the change in myometrial activity is periodic and apparently entrained to the light-dark cycle. In this study the major changes in myometrial activity occurred in the early hours of darkness, although maternal plasma estradiol was elevated throughout the entire day. The mechanism by which estrogens stimulate myometrial contractions remains unclear. Estrogens may alter the population of adrenergic receptors on the myometrial cell, thereby directly influencing myometrial activity.[21] It is possible that other agonists are secreted during the hours of darkness and the estrogens serve merely to lower the myometrial threshold to such putative agonists. Further studies are needed to explore this relationship.

Our study was designed in part to evaluate a possible role for androgen precursors in the increased myometrial activity that accompanies several forms of stress. We postulate that in situations of acute or chronic stress, androgen precursor production rises and may lead to increased estrogen production. In turn, the estrogens stimulate increased myometrial contractility. Further studies are required to prove this hypothesis. An alternative mechanism that would be compatible with our observations is that androstenedione itself induced an increase in myometrial activity. This explanation would

have implications for the role of androgens released from maternal and fetal adrenals during different stress states. This pregnant nonhuman primate model may prove to be useful not only in the study of factors that determine myometrial activity in general, but also with respect to putative mechanisms that can precipiate premature labor.

We thank Ms. Tami Myers and Dr. James Owiny for assistance with the estradiol assay.

Flow cytometry of normal, hyperplastic, and malignant human endometrium

A study of ploidy and proliferative indices including comparison with in vitro S-phase labeling

James G. Thornton, MD,[a] Philip Quirke, PhD,[b] and Michael Wells, MD[b]
Leeds, England

The validity of 48 endometrial proliferative indices derived from flow cytometric deoxyribonucleic acid histograms was tested by comparison with S-phase labeling indices. There was a positive but weak correlation. Despite this correlation, there was a good relationship between the flow cytometric proliferative indices and both the menstrual phase and degree of tissue differentiation in a larger series of 162 normal, hyperplastic, and malignant endometrial specimens examined by flow cytometry alone. Flow cytometric proliferative indices may be useful for prediction of tumor behavior in non-DNA aneuploid endometrial carcinomas that are assessed as being a good prognostic type by other tumor parameters. (AM J OBSTET GYNECOL 1989;161:487-92.)

Key words: Flow cytometry, labeling indices, endometrium, hyperplasia, carcinoma

Endometrial carcinoma is conventionally classified by tumor stage and histologic grade. Other hormone receptor and cell kinetic parameters have been claimed to have prognostic importance, but their detailed relationships to tumor behavior are still uncertain.[1, 2] Tumor kinetic measurements may be performed by labeling of cells in culture with various deoxyribonucleic acid (DNA) precursors or by measurement of the quantity of DNA in individual tumor cells. From the DNA histogram, it is possible to identify diploid cells in the G_0 or G_1 phase of the cell cycle, tetraploid cells in the G_2 phase or mitosis, and to calculate the proportion of cells intermediate between diploid and tetraploid that are presumably in S phase. If there is a second G_0/G_1 population peak of nondiploid cells, the tumor is said to be DNA aneuploid; this second peak interferes with the counting of S-phase cells. Until recently cellular DNA was measured by microspectrophotometric methods,[3] but these are laborious and flow cytometry has superseded them for rapid and precise DNA measurements on large numbers of cells.[4]

In a number of tumor types, flow cytometric measurement of DNA content has identified a DNA aneuploid group with a poor prognosis and a diploid group with a more favorable prognosis.[4, 5] Such studies can be performed on paraffin-embedded tissue,[6] which allows examination of archival material and greatly expedites the development of detailed prognostic indicators. There have been a number of studies of endometrium.[1-3, 7-10] DNA aneuploid tumors appear to have a worse prognosis. Although S-phase fractions were greater in poorly differentiated tumors, the S-phase fraction itself did not correlate with prognosis.[2] However, others have claimed that larger S-phase fractions are associated with more deeply invasive tumors.[10]

Other kinetic parameters such as S-phase labeling indices[11] should provide similar results but are more laborious and require fresh tissue. Experiments to compare flow cytometric proliferative indices with thymidine or bromodeoxyuridine labeling indices have primarily been confined to cell culture systems or animal tumor models.[12, 13]

The purpose of our study was to use such proliferative indices as a prognostic indicator in endometrial cancer. As a preliminary step to a large retrospective study, we report the proliferative indices and ploidy status of normal, hyperplastic, and malignant endometrium. To validate the results, a number of fresh endometrial specimens were labeled in vitro with the thymidine analog bromodeoxyuridine, and S-phase indices were derived and compared with the flow cytometric proliferative indices.

Methods

The study was performed in two parts. First, 48 non–DNA aneuploid endometrial specimens were labeled in vitro with bromodeoxyuridine to derive S-phase in-

dices (I_S). Adjacent portions of the same specimens were examined by flow cytometry. From the DNA histograms, proliferative indices (I_P) were calculated and compared with the I_S values. Second, flow cytometric measurement of ploidy and I_P was performed on another 175 normal and abnormal endometrial specimens obtained from the archives. The histopathologic diagnosis of the fresh and archival cases combined with those of the whole series are listed in Table I. The flow cytometric results are only reported in detail for the 223 normal, hyperplastic, and malignant specimens. Five atrophic and menstrual specimens were included in the first part of the study to test the correlation between I_S and I_P.

Comparison of in vitro labeling and flow cytometry. Forty-eight endometrial specimens were obtained fresh from the operating room. Curettage specimens were immediately placed in phosphate-buffered saline solution (pH 7.4), and adjacent specimens were placed in formalin and routinely processed for histologic examination. The method of bromodeoxyuridine labeling correlates well with thymidine labeling.[11] Briefly, 1 mm^3 pieces of endometrium were incubated for 1 hour at 37° C on grids in phosphate-buffered saline solution containing 2×10^{-4} mol/L bromodeoxyuridine and fixed in Carnoy's solution. Three-micron paraffin sections were denatured in hydrochloric acid and labeled with a monoclonal anti-bromodeoxyuridine antibody by means of an indirect peroxidase technique. A moderately differentiated adenocarcinoma labeled with bromodeoxyuridine is shown in Fig. 1. Labeling indices (I_S) were derived for glands and stroma separately by the following formula:

$$I_S = \frac{\text{Labeled cells}}{\text{Labeled and unlabeled cells}} \times 100$$

Since flow cytometric specimens were not separated into glandular and stromal components, a total specimen I_S was also derived as follows. A 7 μm section was taken from the paraffin-embedded tissue and stained with hematoxylin and eosin. This specimen was adjacent to the 60 μm section used for flow cytometry (see following section). This was examined on a Leitz microscope at ×200 magnification. The relative proportions of glands and stroma were calculated by counting the number of times they were overlaid by the intersections on an eyepiece graticule. An adjusted value for I_S that accounted for the proportions of glands and stroma in the flow cytometric specimen was calculated as follows:

P_{gl} = Proportion of glands
P_{st} = Proportion of stroma
Adjusted specimen I_S = Gland $I_S \times P_{gl}$ + Stroma $I_S \times P_{st}$

Flow cytometry. Adjacent specimens of endometrium were routinely processed in paraffin and, after removal of sections for histology and morphometry, examined by flow cytometry according to a modification of the method of Hedley et al.[6] Sixty-micron sections from paraffin blocks were cut, transferred to glass slides, dewaxed in xylene, rehydrated through graded alcohols (100%, 95%, 90%, 70%, and 50%) and washed twice in water. The tissue was removed from the slide with a scalpel and incubated in 0.9% sodium chloride adjusted to pH 1.5 with 2N hydrochloric acid plus 0.5% pepsin at 37° C in a water bath for 30 minutes. For archival material in which hysterectomy specimens that included myometrium were examined, the nonendometrial portion of the specimen was discarded when the tissue was removed from the glass slide. The cells were centrifuged at 2000 *g* and washed twice in phosphate-buffered saline solution. Cells were stained by incubation at 20° C for 30 minutes in RPMI 1640 tissue culture medium plus 4′-6′-diamidino-2-

phenylindole dihydrochloride 1 μg/ml. The cells were syringed through a 23-gauge needle and filtered through 24 layers of gauze to remove debris.

Samples were analyzed on an EPICS V flow cytometer. Excitation was by a Coherent Inova-90 5W ultraviolet enhanced argon ion laser used at 100 mW and a wavelength of 488 nm. Specimens were rejected if the median half-peak coefficient of variation of the diploid peak was >10%. A minimum of 10,000 nuclei were counted. Typical histograms showing the normal diploid cell population of specimens with low, medium, and high proliferative fractions and the DNA aneuploid histogram of a poorly differentiated carcinoma are shown in Fig. 2. Tumors were recorded as aneuploid only if two G_0/G_1 peaks could be clearly identified.[12] The DNA index of each DNA aneuploid cell population was calculated by measuring its modal channel number and dividing this by the modal channel number of the first diploid G_0/G_1 peak.

Cell cycle analysis. Histogram analysis was performed with a standard program, Para 1. The percent S phase and percent G_2 phase were summed to derive the proliferative index since this has been found to yield more accurate results when samples demonstrating varying percentage coefficients of variation are analyzed. Proliferative indices were only calculated for diploid specimens.

Statistical analysis. Labeling indices and flow cytometric proliferative indices are not usually normally distributed. Therefore correlations between tests were

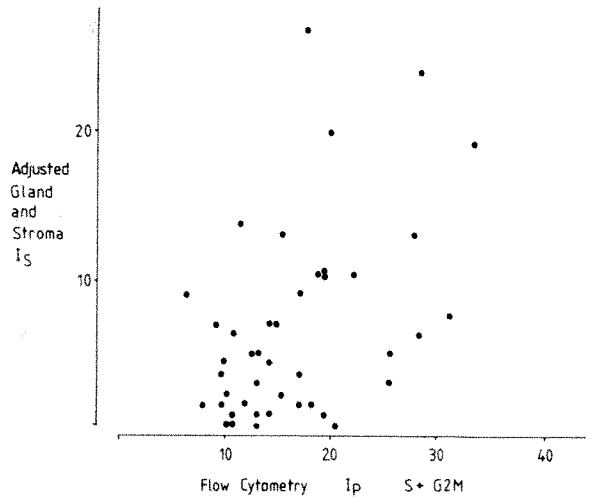

Fig. 3. Plot of bromodeoxyuridine-labeling indices against flow cytometric proliferative indices.

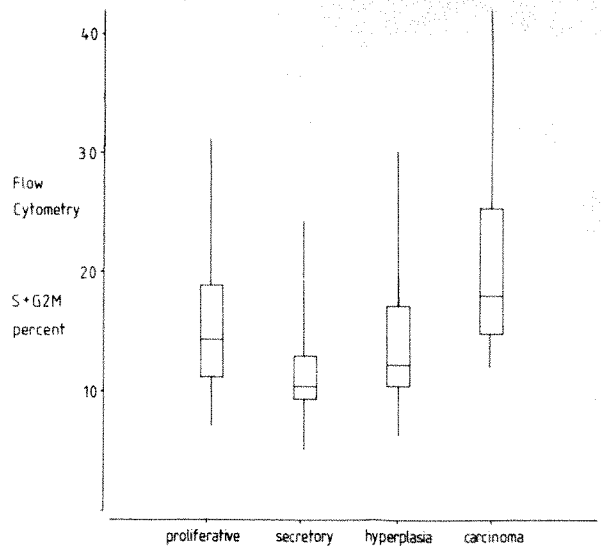

Fig. 4. Flow cytometric proliferative indices for various endometrial types. (Medians, interquartile ranges, and ranges.)

measured with Spearman's rank coefficient. Tests of the significance of differences between paired samples were tested with a Wilcoxon rank-sum test and between unpaired samples using a Mann-Whitney U test. Data analysis was performed using the Statistical Program for the Social Sciences (SPSS^X) version 2.2.

Results

The adjusted specimen labeling indices plotted against the flow cytometric proliferative indices for the 44 diploid specimens examined by both techniques are shown in Fig. 3. Four specimens with adjusted I_S values of 0 were excluded. There is a significant but weak correlation between them ($R = 0.36$, $p < 0.01$). I_P values tend to be higher than I_S. This trend is particularly marked at low levels of I_P when the values are rarely <10%. The median, interquartile ranges, and ranges of I_P for proliferative, secretory, and grouped hyperplastic and carcinomatous specimens are shown in Fig. 4. The median value for proliferative endometrium was 14.3% and for secretory endometrium was 10.3% ($p = 0.0001$), whereas that for hyperplasia was 12.0%, which is only slightly lower than proliferative endometrium ($p = 0.02$). Carcinomas had a median value of 17.8%, which is significantly higher than normal proliferative ($p = 0.002$) and hyperplastic endometrium ($p = 0.0001$). The results for the various subtypes of hyperplasias and of carcinomas are shown in Fig. 5. Although there is considerable overlap, there is a consistent trend toward higher values of I_P being associated with more atypical hyperplasias and less differentiated carcinomas. The histologic features and DNA indices of the 13 DNA aneuploid specimens are listed in Table II. Most aneuploid tumors were well-differentiated carcinomas, but the highest DNA indices occurred in the less-differentiated carcinomas.

Comment

Our study has shown by flow cytometry that proliferative indices in normal endometrium are related to the phase of the menstrual cycle and, in malignant endometrium, to the degree of differentiation. Although the correlation with S-phase labeling indices provides some confirmation of the validity of the flow cytometric measurements, it also demonstrates that flow cytometry appears to be a relatively crude method of measuring proliferative indices when this cell cycle program is used.

There are several possible causes for the poor correlation between flow cytometry and S-phase labeling. First, although care was taken to correct the I_S values for the proportion of gland and stromal tissue in the flow cytometric specimens, it was not always possible to exclude myometrial contamination. In normal endometrium, myometrium was removed from the thick tissue sections before analysis by flow cytometry, but removal was not always possible in tumor or curettage specimens in which myometrium and endometrium were intimately mixed. Second, flow cytometric measurements of proliferative indices rely on the assumption that cells with a DNA content above an arbitrary value are in S phase. Unless the coefficient of variation of DNA content is 0, it is inevitable that some G_0/G_1 cells at the upper end of the normal distribution will be misclassified. Third, there may be some cells with a genuine S-phase DNA content that are not actually synthesizing DNA, the so-called S_0 cells. These have been clearly demonstrated in cell culture[13] and in mouse tumors.[14] Such cells are recorded as S phase on flow cytometry, but do not take up the bromodeoxyuridine label on culture. We are now investigating whether such

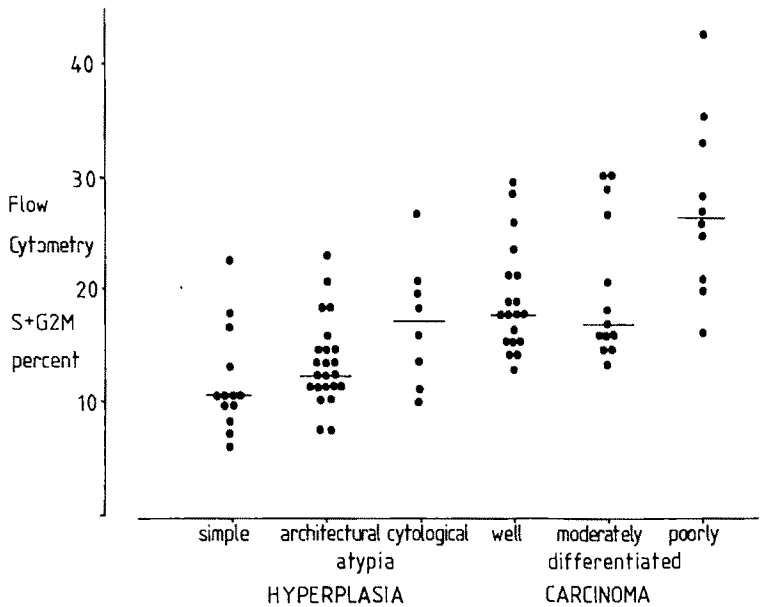

Fig. 5. Flow cytometric proliferative indices for the various subtypes of endometrial hyperplasia and carcinoma. (*Horizontal lines* represent median values.)

a cell population exists in endometrium by dual-channel flow cytometry of bromodeoxyuridine-labeled tissue. A fourth source of error may be that the bromodeoxyuridine-labeling method underestimated the number of S-phase cells in some specimens because of necrosis, poor oxygenation, or poor penetration of the nucleotide in culture. Necrosis did occur in some carcinomas, but we do not believe that it was a major factor in our study because all cases with a labeling index of 0 were excluded from analysis. Finally, the I_F value is somewhat higher than I_S because all G_2 cells and approximately half of cells in mitosis are included as well.

Similar work has been performed on breast tumors by McDivitt et al.[15] They compared thymidine-labeling indices with flow cytometric S-phase calculations by means of the same histogram analysis program (Para 1) and obtained an excellent correlation of $R = 0.8$ when collagenase digestion was used but only $R = 0.6$ when mechanical dissociation was used. These correlation coefficients are better than those obtained in our study. One explanation may be that McDivitt et al.[15] performed the flow cytometry on fresh tissue and obtained lower coefficients of variation.

There have been a number of studies of flow cytometry of endometrium, but most have concentrated on measurements of ploidy and none have compared proliferative indices with labeling indices. Two studies have shown that normal endometrium is always diploid and that mean S-phase fractions are greater in normal proliferative (9.7%) than secretory endometrium (6.2%)[8] but less than in carcinomas.[7] There is only one previous report of flow cytometric S-phase fractions in hyperplasia.[16] In nine cases of cystic hyperplasia, mean S-phase fraction was 3.4%, in six cases of "adenomatous" hyperplasia it was 4.8%, and in five carcinomas, 4.8%. In endometrial carcinomas, S-phase fractions were greater in poorly differentiated than well-differentiated tumors.[1, 8]

Table II. DNA indices of 13 aneuploid endometrial specimens

Histologic features	*No.*	*DNA indices*
Cystic hyperplasia	1	1.30
Architectural atypia	2	1.20, 1.42
Well-differentiated carcinoma	7	1.15, 1.16, 1.26, 1.27, 1.31, 1.42, 1.52
Moderately differentiated carcinoma	2	1.17, 1.75
Poorly differentiated carcinoma	1	1.71

The rate of DNA aneuploidy among endometrial carcinomas in our study (9 of 43) is slightly lower than most previous reports that estimate a rate of approximately 30%.[1, 3, 7, 8, 10] According to two groups, DNA aneuploidy was more common among low-grade tumors,[7, 8] but this was not shown in the smaller study by Geisinger et al.[1] DNA aneuploid tumors appear to have a worse prognosis than diploid tumors,[7, 10] and it has been claimed that DNA ploidy is a better prognostic indicator than tumor grade, depth of invasion, or even estrogen receptor concentration.[2] The finding of one aneuploid case of cystic hyperplasia and two of aneuploid hyperplasia with architectural atypia has not been

previously described but may represent cases with an increased malignant potential. One preliminary report suggested that the proliferative indices in carcinomas may also be predictive of a poor prognosis,[10] but this has not been confirmed.[2]

Therefore it is clear that the rate of DNA aneuploidy in endometrial carcinomas is lower than in most other nonhematopoietic malignancies in which 50% to 80% are DNA aneuploid.[5] Like other parameters of endometrial malignancy, ploidy may be a poor discriminator of the majority of well-differentiated good prognosis carcinomas, and proliferative indices may be better. It remains to be determined whether flow cytometric proliferative indices or S-phase labeling indices are better predictors of tumor behavior, but a major advantage of flow cytometric measurements is that they can be performed retrospectively on stored tissue and are much less time consuming than culture techniques.

We thank Mrs. C. A. North and Mr. R. Stretton for technical assistance.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1989 issues from the Publisher, at a cost of $56.00 ($79.00 international) for Vol. 160 (January-June) and Vol. 161 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C.V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146-3318, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Atrial natriuretic peptide receptors in guinea pig placentas

Christos G. Hatjis, MD, and David M. Grogan, BA
Winston-Salem, North Carolina

The multiple physiologic effects of atrial natriuretic peptide are mediated through specific atrial natriuretic peptide plasma membrane receptors. We have attempted to determine whether atrial natriuretic peptide receptors are present in guinea pig placentas and subplacentas at approximately 45 and 65 days' gestation. A microsomal plasma fraction was prepared from each component. Atrial natriuretic peptide receptors were detected by in vitro radioligand techniques with α-human atrial natriuretic peptide labeled with iodine 125. In placentas we identified one set of specific binding sites for atrial natriuretic peptide at both gestational ages. Although the maximal concentration of the receptors did not change with advancing gestation, the dissociation constant was higher at 65 than at 45 days' gestation. In subplacentas two sets of binding sites were identified, one of low capacity–high affinity and the other of low affinity–high capacity. The maximal concentration of the atrial natriuretic peptide receptors did not change as a function of gestation. However, the dissociation constant, for both the high- and low-affinity sites, significantly decreased with advancing gestation. (Am J Obstet Gynecol 1989;161:493-6.)

Key words: Atrial natriuretic peptide receptors, guinea pig placentas, guinea pig subplacentas

Atrial natriuretic peptide (ANP) is a hormone or a group of hormones that is secreted by specialized cells in atrial myocytes in many species.[1] The presumed active peptide in humans is designated α-hANP.[2] Although the exact physiologic or pathologic role of ANP has not been elucidated, this peptide has been shown to be a potent natriuretic, diuretic, and vasodilatory agent.[3] The multiple effects of ANP appear to be mediated through specific membrane receptors.[4] We and others have identified specific receptors for ANP in various mammalian organs, including human placentas.[5-7] There is no information about ANP receptor properties in placentas obtained from pregnant guinea pigs. Moreover, guinea pig placentation is unique with regard to the presence of subplacentas.[8] In addition to their endocrine, respiratory, and nutritional functions, guinea pig placentas and subplacentas may be involved in fluid and electrolyte homeostasis. If placental ANP receptors are present in several species showing different types of placentation, then one could infer that they may be involved in important aspects of placental function across species. Thus we have attempted to determine whether specific ANP receptors can be detected in plasma membranes from placentas and subplacentas of pregnant guinea pigs at 45 and 65 days' gestation.

Material and methods

Material. Nonradioactive α-hANP (124-151) was obtained from Peninsula Laboratories. α-hANP labeled with iodine 125 was obtained from Amersham and was used fresh on a monthly basis. The other reagents were obtained commercially and were of the highest purity available.

Tissue. Primigravid Hartley guinea pigs with time-dated gestations were put to death under xylazine and ketamine anesthesia at 40 to 45 days' gestation or at 60 to 65 days' gestation (term, 65 days). At hysterectomy, placentas and subplacentas were obtained from four animals at each gestational age. The tissue was snap-frozen in liquid nitrogen and stored at −70° C. Under these conditions no significant loss in ANP receptor activity was noted with freezing and storage for up to 6 months.

Membrane preparations. Membrane preparation of a plasma membrane fraction was done as previously described.[5-7] On the day of the assay approximately 2 to 5 gm of either placenta or subplacenta was allowed to thaw in 10 to 20 ml of ice-cold 0.9% sodium chloride, 20 mmol/L Tris hydrochloride, 250 mmol/L sucrose, 5 mmol/L ethylenediaminetetraacetic acid (EDTA), and 0.6 mmol/L phenylmethylsulfonyl fluoride (PMSF), pH 7.5. All subsequent procedures were carried out at 4° C. The tissue was minced with scissors and subsequently homogenized with a Brinkman Polytron blender on setting No. 7, twice, with each cycle

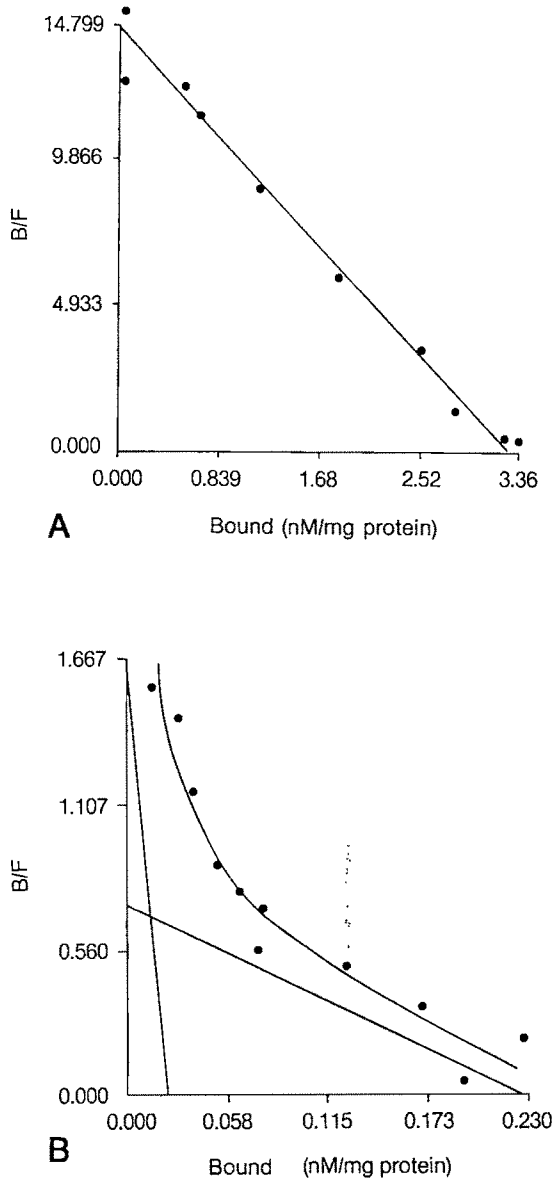

Fig. 1. Representative binding curves of ^{125}I-α-hANP to guinea pig placenta **(A)** and subplacenta **(B)** at 65 days' gestation. Each point was determined in triplicate.

lasting approximately 45 seconds and a 20-second cooling period between homogenizations. This crude homogenate was then centrifuged at 600 *g* for 15 minutes. The resultant pellet was discarded and the supernatant was centrifuged at 12,000 *g* for 30 minutes. The supernatant of the above was centrifuged at 40,000 *g* for 40 minutes and the pellet was resuspended in 50 mmol/L potassium phosphate (pH 7.5, 2 mmol/L EDTA and 0.6 mmol/L PMSF) on the Brinkman Polytron blender at setting No. 7 for 15 seconds. This suspension was then centrifuged at 40,000 *g* for 40 minutes twice and the final pellet was resuspended in the incubation buffer of 50 mmol/L potassium phosphate, 2 mmol/L EDTA, 0.6 mmol/L PMSF, 0.1% bacitracin, and 1 μmol/L aprotinin (pH 7.5) in a volume that gave a final concentration of 11 to 23 μg per tube.

ANP receptor assay. Placental and subplacental plasma membranes were incubated at 25° C for 45 minutes in the presence of ^{125}I-ANP with or without unlabeled α-hANP. Preliminary experiments had shown that ANP binding to placental membranes achieved equilibrium by 20 minutes of incubation and was stable for at least 90 minutes. ^{125}I-ANP was present at concentration of 10 to 15 pmol/L. Unlabeled α-hANP was present in concentrations ranging from 10^{-13} to 10^{-7} mol/L. The latter concentration (10^{-7} mol/L) was designated as nonspecific binding. α-hANP was diluted in 0.1% acetic acid and 0.2% bovine serum albumin. Polypropylene tubes were used throughout. The total volume of incubation was 250 μl.

At the end of incubation, 4 to 5 ml of incubation buffer without the additives was used to stop the reaction. The tubes were decanted into pressure manifolds containing GF/C (Whatman) filters presoaked in 1% polyethylenimine and 1% bovine serum albumin. These filters were then washed in 15 ml of buffer, dried, and counted in a γ-counter (Packard Auto Gamma, efficiency 80%).

We used a competitive binding assay of displacement of ^{125}I-α-hANP by α-hANP to arrive at Scatchard plots.[9] These were then analyzed by LIGAND.[10] The dissociation constants, K_d, and maximum binding capacities, B_{max}, were calculated for each one of the curves. The results are expressed as mean ± SEM. The amount of protein in the assay was determined by the method of Bradford,[11] with bovine serum albumin used as the standard.

The parameters of interest, (K_d and B_{max}), were compared by two-tailed t test. A $p < 0.05$ was considered as significant.

Results

Fig. 1 shows representative binding curves for placental *(A)* and subplacental *(B)* ANP receptors of an animal at 65 days' gestation. Similar results were obtained in the other animals studied. We detected ANP receptors in the microsomal fraction in all cases. The binding was specific, saturable, and was inhibited by

Table II. Binding characteristics* of ANP receptors in guinea pig subplacentas

Gestational age	K_H *(pmol/L)*	K_L *(nmol/L)*	R_H *(pmol/L/mg protein)*	R_L *(nmol/L/mg protein)*
45 days (n = 3)	86.97 ± 8.86†	6.14 ± 3.78‡	15.90 ± 5.10	0.094 ± 0.032
65 days (n = 3)	21.23 ± 4.10	0.56 ± 0.28	27.95 ± 24.48	0.228 ± 0.200

Statistical analysis for R_H and R_L was performed after log transformation. n, Number of animals studied.
*K_H and R_H, K_d and B_{max} for high-affinity site. K_L and R_L, K_d and B_{max} for low-affinity site.

increasing the concentration of unlabeled α-hANP. Note that in the placental component one set of binding sites is seen as opposed to the subplacental fraction, which demonstrates two sets of receptors for α-hANP. Table I shows the calculated K_d and B_{max} from replicate experiments in guinea pig placental tissues at 45 and 65 days' gestation. In all cases there appears to be one set of receptors for α-hANP that shows a uniform high affinity and low capacity. Statistically, the best curve fit is obtained when one set of ANP binding sites is postulated to be present. Of interest is the observation that the K_d increases with advancing gestation, suggesting a decrease in the affinity of the placental ANP receptor for α-hANP.

Table II shows the calculated K_d and B_{max} from replicate experiments in guinea pig subplacentas. In all cases there appear to be two sets of receptors for α-hANP that show high-affinity/low-capacity and low-affinity/high-capacity binding characteristics, respectively. Statistically, the best curve fit is obtained when two sets of binding sites are postulated to be present. Although the B_{max} for either the high- or low-affinity site does not change with advancing gestation, in contrast to the observations with placental tissue, K_d for the high- and low-affinity binding sites decreased from 45 to 65 days' gestation, suggesting an increase in the affinity of the subplacental ANP receptor to α-hANP.

Comment

This is the first instance where ANP receptors have been reported in guinea pig placentas and subplacentas. These observations extend our previous results concerning human placentas[7] and sheep cotyledons.[12] These results strongly suggest that placental ANP receptors are found in species with different types of placentation (from both the functional and the morphologic standpoint).

Similar to the situation in human placentas,[5, 7] one set of binding sites is found in guinea pig placentas. Although we do not have any information regarding the ontogenesis of ANP binding sites in human placentas with advancing gestation, in pregnant guinea pigs there appears to be a decrease in the affinity of the placental ANP receptor from 45 to 65 days' gestation. However, it should be noted that these studies were conducted at only two time points—midpregnancy (45 days) and term (65 days). Finally, whether this change represents a primary effect or is secondary to an increase in circulating ANP concentrations is not known.

Pregnant guinea pigs are the only mammals that show a subplacental structure.[8] The latter has been thought to be involved in fluid and electrolyte homeostasis. Interestingly, ANP receptors are present in the microsomal fraction from subplacentas. In contrast to the situation in the placental ANP receptors, two sets of binding sites are observed. Although the maximal concentration of these binding sites is unchanged as a function of gestation, there is an increase in the affinity of these binding sites for α-hANP from 45 to 65 days' gestation. We doubt that the presence of these two sets of binding sites reflects the use of a probe that was developed from human material, since only one set of binding sites was seen in guinea pig placentas. ANP receptor heterogeneity has been previously reported in other tissues and species.[2] Thus a plausible explanation might be that the presence of two sets of binding sites reflects actual functional receptor subpopulations in guinea pig subplacentas.

The change in placental and subplacental ANP receptors from 45 to 65 days' gestation in pregnant guinea pigs could be a primary effect or could be secondary to changes in circulating ANP concentrations in the maternal and fetal compartments. However, very little is known about circulating levels of ANP in pregnant or nonpregnant guinea pigs. Further purification of the placental and subplacental ANP receptors will be necessary to rule out the contribution of an intrinsic change in ANP receptors. This work represents the necessary first step toward the latter goal.

The presence of ANP receptors in placental and subplacental plasma membrane fractions is interesting in that it suggests that ANP may have significant effects on placental hemodynamics, fluid shifts, and electrolyte

transport, as well as endocrine function. There is a paucity of in vitro or in vivo experiments to support this hypothesis. However, in a preliminary report in human placentas, ANP appears to modulate sex steroid production.[13] Further experiments need to be performed to define the functional implications of ANP receptors in guinea pig placentas and subplacentas.

CORRESPONDENCE

Attempted suicide and pregnancy

To the Editors:

It was interesting to read the article written by D. Lester and A. T. Beck (Attempted suicide and pregnancy. AM J OBSTET GYNECOL 1988;158:1084-5) with regard to 15 consecutive pregnant women because we have had experience with >500 cases in Hungary. There is only one hospital for the provision of health care to chemically poisoned adult inhabitants of Budapest and the surrounding area, which involves 3 million people. The number of hospitalized cases of poisoning is about 10,000 annually. More than 90% of the cases involve self-poisoning (i.e., suicide attempts). There is an obvious preponderance of women and among them are pregnant women. Our purpose was to find a human experimental epidemiologic model for the study of teratogenicity of high doses of drugs and other chemicals.[1]

The first project consisted of 209 poisoned pregnant women who were hospitalized between 1960 and 1979.[2,3] Of these 37% were unmarried. The main reasons of suicide attempts were as follows: familial troubles that mainly involved the potential loss of a lover (78%), economic crisis (9%), unwanted pregnancy or a desire for abortion (13%). Higher rates of stillbirths, mental retardation, and behavioral deviation and a lower mean birth weight as a result of fetal growth retardation were found in the offspring. However, an increased occurrence of spontaneous abortions, congenital abnormalities, and infant deaths was not detected.

In the second project the behavioral development of offspring and their sibs in 176 self-poisoned pregnant women hospitalized in 1980 to 1984 was studied. The aim of this approach was to separate the familial-maternal sociocultural effect in postnatal life and the biologic-teratologic effect of self-poisoning in prenatal life.[4]

Since 1985 a very sensitive pregnancy test has been performed in the third project in all poisoned women from ages 14 to 50 years. The annual total numbers of self-poisoned pregnant women ranged from 76 to 102 in 1985 to 1987. These pregnancies and offspring development are being followed-up. Most of the suicide attempts occurred at the earliest inapparent phase of pregnancy. The incidence of so-called *chemical pregnancies* is significantly higher[4] and the rates of chromosome breakages and sister chromatid exchanges in self-poisoned pregnant women were significantly lower than in nonpregnant self-poisoned women.[5] It indicates some protective effect of pregnancy concerning mutagenic factors.

The purpose of this letter is to give some information about these studies and to call for collaboration in the evaluation of the data base.

Sperm antibodies and infertility

To the Editors:

The excellent report by Witkin and David (Effects of sperm antibodies on pregnancy outcome in a subfertile population. AM J OBSTET GYNECOL 1988;158:59-62) deserves high praise for giving emphasis to the significance of sperm antibody in relation to infertility. They have also, quite correctly, urged gynecologists to give more consideration to this possible etiologic factor. I would add to their arguments the concept that the occasional occurrence of pregnancy despite the presence of sperm antibody is no more an argument against the antibody's significance than is the occasional pregnancy that occurs despite mild endometriosis or moderate oligospermia, or other such conditions. These are still the exceptions, not the rule. As the authors say, furthermore, these pregnancies usually are quite delayed, hence, do *not* represent normal fertility.

I am gratified that they found a significant difference in the incidence of sperm antibody in women who are infertile (38%) and those who are fertile (12%). If we subtract one value from the other, we obtain 26%,

which could be taken as their infertile value if the "background" fertile value were zero. They made use of an enzyme-linked immunosorbent assay (ELISA) to detect this antibody. In our work with sperm agglutination, we reported in 1975 an incidence of 18% in infertile women, and we found 1% or 2% in the fertile group.[1] The moderate degree of difference may be because of the difference in methods, but also, the rather small number of samples that they studied (as they point out).

However, we do have a disagreement concerning the study of men. Witkin and David found no distinction between infertile and fertile groups, whereas we found a 9% incidence among the infertile men and a ≤1% incidence in the fertile group.[1] Others have found the same value, namely, 8% to 10%, as was recently reviewed.[2] There may need to be more studies on the ELISA technique itself. These authors have used the individual sperm from the patient or the patient's partner as the target antigen; other workers have used pools of sperm—not only pooled but unrelated to the patients.[3,4]

The authors put great emphasis on the desirability of the use of "purified, living, and motile spermatozoa." However, in the ELISA procedure, they are certainly dead sperm, in contrast (we may point out) to those in sperm agglutination assays in which the sperm cells are living and motile (even if not purified) during the procedure. I suppose that they mean that their test sperm *had* been "purified, living, and motile." However, this does raise a question. Did they also use sperm preparations that had *not* been purified (as by their swim-up procedure), to compare the results of at least some of their sera? In fact, did they also try to use completely immotile sperm? It would be interesting to know how much change in ELISA results this would cause.

As a different point, their finding that sperm antibodies have an association with miscarriage is very interesting and provocative. Here they would have some support from the similar conclusions reported by Haas et al.[5]

Finally, their comments with regard to prednisone treatment would seem to suggest some degree of success for this treatment. Our study with methylprednisolone did show a very good success rate,[6] as did also the work of Hargreave.[7] I would welcome more details eventually on the outcome of their steroid medication efforts.

Reply

To the Editors:

Sperm antibody testing of infertile couples will gain acceptance among clinicians only when physicians can be assured that the analysis measures antibodies that are relevant to infertility. It is because of this that assays that directly measure immunoglobulin reactivity with living, motile sperm (Immunobead binding,[1] mixed antiglobulin reaction,[2] radioimmunoassay,[3] and enzyme-linked immunosorbent assay or ELISA[4]) are rapidly replacing assays that measure a secondary consequence of antibodies (sperm agglutination and immobilization). Inasmuch as antibodies that neither agglutinate nor immobilize sperm can nevertheless interfere with fertility,[5] and agglutination of sperm can occur in the absence of antisperm antibodies,[5] reliance on these latter two assays will yield a significant number of false-positive and false-negative results.

Our article presented data suggesting that only antibodies on the surface of ejaculated sperm, and not antisperm antibodies present in a man's serum, correlated with infertility.[4] Other studies have demonstrated a lack of correlation between antisperm antibodies in serum and in semen.[6-8] Naturally, if circulating antibodies never come into contact with sperm they can have no effect on fertility. Therefore the direct analysis for antibodies on the sperm surface appears to be the preferred procedure to detect relevant antibodies in men.

A purified population of living motile sperm were reacted with patients' sera in our assay. Fixation of sperm to wells of a microtiter plate was performed *after* their incubation with serum. As shown previously, the ELISA assay correlates with the Immunobead assay only when the ELISA employs purified and motile sperm free in solution.[9]

The issues of treatment for immunologic infertility can be addressed only after vaid antisperm antibody detection assays are performed. If the antisperm antibodies that are detected are not relevant to infertility, then any treatment will be ineffective.

Vaginosonographic examination—Routine procedure?

To the Editors:

The article by Bernaschek et al. (Bernaschek G, Rudelstorfer R, Csaicsich P. Vaginal sonography versus serum human chorionic gonadotropin in early detection of pregnancy. AM J OBSTET GYNECOL 1988; 158:608-12) refers to the use of a vaginal transducer to diagnose pregnancy as early as 4 weeks and 2 days and for early diagnosis of ectopic pregnancy. The authors suggest repeating the scan within 2 days if the initial study is equivocal. Unfortunately, they make no unequivocal reference to a need for patient selection. In view of their emphasis on the suitability of vaginal scanning as an office procedure, it could be interpreted as suggesting that this is a reasonable means of routine diagnosis of pregnancy. It is totally inappropriate to publish such an article without any cautionary comment with regard to the safety of ultrasonography.

Reply

To the Editors:

The allegations center on three issues: (1) safety of ultrasound; (2) need for patient selection for repeat scans; and (3) reasonable means of routine diagnosis of pregnancy.

1. The energy output of this modern vaginal ultrasonographic transducer is well beyond the safety margins of the American Institute of Ultrasound in Medicine (i.e., considerably <100 mW/cm²). The recommendations of the World Federation of Ultrasound in Medicine and Biology are not based on scientific evidence that ultrasound delivered clinically is deleterious, but rather on the realization that scientific evidence is inconclusive. To date, studies with negative results predominate. Nevertheless, exposures should be as short as possible and administered by qualified personnel.[1]

2. An indication for a repeat scan after 2 days is only suggested when no intrauterine gestational sac has been seen in connection with a positive pregnancy test (<750 mIU/ml) and the absence of any clinical evidence of spontaneous abortion.

3. In consideration of the very low energy output and the great value of a definite identification of an intrauterine pregnancy, we believe that vaginal ultrasonography is a new means for routine diagnosis of early pregnancy. There are patients for whom the very early diagnosis of an intrauterine pregnancy is of great value (e.g., patients with first-trimester bleeding or with a history of ectopic pregnancy, pelvic inflammatory disease, or tubal surgery or after in vitro fertilization).[2]

Finally, years ago the monitoring of follicles was introduced into fertility praxis with the same equipment without any reported hazard to the oocytes.

Nerve entrapment after Pfannenstiel incision

To the Editors:

I was surprised to read the conclusion made by Sippo et al. (Nerve entrapment after Pfannenstiel incision. AM J OBSTET GYNECOL 1987;157:420-1) that entrapment of the iliohypogastric nerve is a common complication of the Pfannenstiel incision. Because the authors have not reported the total number of patients who had undergone a Pfannenstiel incision, the prevalence rate of nerve entrapment after Pfannenstiel incision in their patients cannot be calculated. Thus, their statement that "entrapment of the iliohypogastric neve is a common complication of the Pfannenstiel incision" might be a result of their beliefs rather than a conclusion based on statistical calculations.

We perform each year at the Soroka Medical Center in Beer-Sheva, Israel, some 700 laparotomies by the Pfannenstiel incision and have never encountered such a complication. However, I must admit that we have

not actively sought this complication in our patients. Nevertheless, I agree with the authors' recommendations that the Pfannenstiel incision should be extended through the external oblique aponeurosis only and should not involve incision of the internal oblique muscle, and that widely placed corner sutures should be avoided in the closure of the anterior fascia.

Reply

To the Editors:

As you have pointed out, the true incidence of nerve entrapment after Pfannenstiel incision is not known, nor can it be estimated by our preliminary work. However, the fact that nine cases were identified within a 16-month period suggests that this entity is prevalent and could more commonly be identified if physicians who perform large numbers of Pfannenstiel incisions actively sought a history of its symptoms in their postoperative patients.

Why we were first to describe this entity, only fate can explain. But since the publication of this article we have received correspondence from physicians and patients who suggest that this syndrome is real and universal.

Our investigation arose from the serendipitous recognition that the hysterectomized women who have what our gynecology colleagues had termed a "psychosomatic post hysterectomy syndrome," in fact had complaints that closely resembled the symptoms of the nerve entrapment seen after inguinal herniorrhaphy. Until we looked closer at these patients who had been within our midst all along, the true organic source of their symptoms had remained unrecognized and misdiagnosed as psychosomatic. This phenomenon may be compared with mitral valve prolapse, which, although unheard of even 20 years ago, is now recognized to be present in 10% to 15% of the population because it has been described and is actively sought on examination.

It is large centers like yours that do a significant number of procedures with Pfannenstiel incision that will show us how prevalent this nerve entrapment syndrome really is, but only if the residents and staff earnestly consider nerve entrapment and look for it.

Another factor that may be deceptive as to the actual extent of this problem is that the patients who have symptoms remote from the time of surgery may consult their primary care physician first and not their gynecologist or surgeon. In our article (Sippo WC, Burghardt A, Gomez AC. Nerve entrapment syndromes from lower abdominal surgery. Fam Pract 1987;25: 585-7) we emphasized this point with the hope that primary care physicians might consider nerve entrapment as a possible source of lower abdominal pain in patients with a history of surgery.

Perhaps the most important lesson we can learn from this matter is what my Mentor urged us to do as residents: "Believe what the patient tells you and assume it to be so, for the patient has no reason to lie. You may be surprised at what you find if you look hard enough."

Unexplained elevated maternal serum α-fetoprotein level associated with third-trimester problems

To the Editors:

I would like to raise a question with regard to a personally observed association between unexplained elevated maternal serum α-fetoprotein level and third-trimester high-risk pregnancy problems.

In following up delivery outcomes of patients in whom I performed genetic amniocentesis in my Maternal Serum α-Fetoprotein Program Follow-up Center, which is approved by the California State Health Department, I have observed problems in the third trimester: (1) premature separation of the placenta, (2) toxemia, (3) premature labor, and (4) unexplained stillbirth.

If this is more than just a personal experience, should not maternal serum α-fetoprotein pregnancy screening be indicated not only as a screening test for neural tube and other defects such as chromosomal disorder (Down syndrome) but also as a predictor for potential third-trimester high-risk problems?

The issue is not only one of concern for professional liability but also potentially one of compliance. It may be easier to obtain compliance for maternal serum α-fetoprotein screening if the presentation to the patient for justification is not just screening for birth defects, which has a connotation of being associated with pro choice and the subsequent implications for termination of pregnancy. The possibility of premature labor might permit obstetricians to recommend the test in patients who have had previous premature labor, toxemia, unexplained stillbirth, premature separation of the placenta, and intrauterine growth retardation, and focus on that as the primary justification for the test.

The next problem that would surface is what to do and what to recommend if the patient has an unexplained elevated maternal serum α-fetoprotein value. Would genetic amniocentesis automatically be necessary if the fetal ultrasonogram did not reveal a neural tube or other related defect?[1]

Neurofibromatosis and pregnancy

To the Editors:

We congratulate Dr. Blickstein et al. on their detailed review (The obstetric perspective of neurofibromatosis. AM J OBSTET GYNECOL 1988;158:385-9) in which they consider the obstetric problems involved with neurofibromatosis. However, we believe that two problems should receive more attention.

The authors pointed out that the incidence of nontoxemic hypertension is in conflict. To differentiate between primary arterial hypertension, renal hypertension (renal arterial stenosis), pheochromocytoma (paroxysmal hypertonic crises), hypertension because of hyperthyroidism, and hypertension as a symptom of preeclamsia, the following laboratory tests should be performed routinely: plasma renin, 24-hr urine catecholamines, vanillylmandelic acid, homovanillic acid, aldosteron, angiotensin, triiodothyronine and thyroxine. Additionally, we recommend ultrasonography of the heart and the kidneys for these high-risk pregnant patients.

We agree with the authors that even in these women vaginal delivery should be attempted. Because of hypertension, continuous peridural analgesia should be performed analogous to preeclamptic patients.[1, 2] However, if there is any intraspinal lesion (e.g., meningioma), indication for continuous peridural analgesia may not be given. If cesarean section is required, anesthesia should be primarily focused on the patient's hypertension. Therefore specific interactions of perioperatively administered antihypertensive drugs, anesthetics, and narcotics must be emphasized. Hypersensitivity of these patients to muscle relaxation agents must be considered to schedule postoperative care.[3]

Reply

To the Editors:

We thank Drs. Mitterschiffthaler and Fuith of Austria for their informative comment. We agree that their recommendations for laboratory and ultrasonographic tests may help in the differential diagnosis of the conflicting problem of nontoxemic hypertension in pregnant patients with neurofibromatosis.

Because the literature is scant that considers labor of patients with neurofibromatosis, one must rely on one's own clinical judgment. We therefore welcome the suggestion of continuous peridural analgesia in hypertensive neurofibromatosis parturients. Continuous peridural analgesia, however, may be found to be technically difficult to perform in cases complicated by scoliosis.

After the publication of our review, we propose a worldwide study of the reproductive performance of as many patients with neurofibromatosis as possible. Perhaps we could take this opportunity to invite our colleagues to participate in this project.

Isolation of human immunodeficiency virus from the placenta or from maternal blood contaminating the placenta?

To the Editors:

The title of the case report by Drs. Hill, Bolton, and Carlson (Isolation of acquired immunodeficiency syndrome virus from the placenta. AM J OBSTET GYNECOL 1987;157:10-1) seems misleading.

Although the authors pointed out that "The positive viral culture of the placenta was probably a result of the patient's positive blood culture," they nevertheless claim that they isolated the virus from placental tissue. The figure that shows a human T-lymphocyte with extra cellular human immunodeficiency virus simply suggests that the human immunodeficiency virus is in proximity to a lymphocyte. This does not support the contention that the virus had infected placental tissue. Both the lymphocyte and the alleged virions were quite likely from maternal blood.

The authors also might have emphasized that maternal antibodies pass to the fetus as immunoglobulin; thus the fetus has positive serologic test results whether they screen with tests that are simple, cheap, and sensitive (enzyme-linked immunosorbent assay) or complex, expensive, and specific (Western blot). Thus we expect seropositivity in neonates with waning titers over time. A waxing titer would suggest neonatal infection, now anticipated in 50% of children born to infected women. In future reports it would be important to state whether the neonatal serologic tests are performed at birth or at intervals of 6 months or later to assist the reader in knowing whether the positive test results may be because of passive maternal antibody transfer.

The authors do not indicate whether they made any attempt to remove maternal blood from the placenta. (We are not aware of any technique in which this could be accomplished completely.) Therefore their conclusion that the positive test results were probably caused by maternal blood seems to be correct.

In this case the report would have been better titled "Maternal blood contaminates placenta and makes this organ infectious for whatever agents maternal blood may contain."

Reply

To the Editors:

We appreciate the comments of Dr. Greenspoon with regard to our case report of the "Isolation of acquired immunodeficiency syndrome virus from the placenta." Dr. Greenspoon makes several valid points. However, the human immunodeficiency virus (HIV) was isolated from the placenta of this patient. Therefore, the case report was titled "Isolation of acquired immunodeficiency syndrome virus from the placenta." As we pointed out in our report, this was probably a result of the patient's positive HIV status. Because the maternal HIV antibodies are immunoglobulin G, they do always pass to the fetus. Therefore our neonate will initially have positive serologic test results. Over time, which appears to be 9 to 15 months, the titers may wane.

As pointed out by Dr. Greenspoon, in approximately 50% of children born to HIV-positive women, the neonate will have an HIV infection. The test performed in our neonate was at birth and was therefore positive. The infant showed no HIV antibodies at 8 months of age. Unfortunately, both parents have died from acquired immunodeficiency syndrome. The infant is now asymptomatic and 3 years old. The serologic status is HIV negative.

There was an attempt to remove maternal blood from the placenta; however, as Dr. Greenspoon indicated, this cannot be accomplished completely. Finally, it is important to remember that maternal blood does contaminate the placenta and makes this organ infectious for whatever agents maternal blood may contain. This includes HIV, hepatitis, or other infectious agents. As health care providers we should remember this fact and properly dispose of the placenta.

Race and gender factors omitted from results

To the Editors:

I read with interest the article by Goldstein et al. (Goldstein I, Lockwood C, Belanger K, Hobbins J. Ultrasonographic assessment of gestational age with the distal femoral and proximal tibial ossification centers in the third trimester. Am J Obstet Gynecol 1988; 158:127-30).

After the development of x-ray film, Pozier (1912)[1] and Adair and Scammon (1921)[2] studied the osseous development of the knee joint in newborn infants. From these studies it was determined that the distal femoral epiphysis usually did not appear until after the seventh lunar month, was present in 50% of the fetuses at 32 weeks' gestation, 84% at 36 weeks' gestation, and 95% at 40 weeks' gestation. The proximal tibial epiphysis appeared in the ninth lunar month and was present in 41% of the infants at 40 weeks' gestation.

In 1949 Christie,[3] who studied 1112 single born neonates, noted that the presence of the distal femoral epiphysis was correlated with birth weight, sex, and race. If the fetus was <2000 gm, distal femoral epiphyses were present in 9% of white males, 18% of black males, and 50% of white or black females. Between the weights of 2000 gm and 2499 gm, 75% of white males, 89% of black males, 92% of white females, and 94% of black females had distal femoral epiphyses present. If >3000 gm, 85% of white males, 91% of black males, 98% of white females, and 99% of black females had distal femoral epiphyses present.

Classical teaching stresses that there is greater maturity of female infants as compared with male infants, and of black infants as compared with white infants of equal weights.

It would appear that the results from the study by Goldstein and his co-workers would be more meaningful if the sex and race of the fetuses they studied were given. If there were no differences, this should be stated.

Reply

To the Editors:

My colleagues and I are grateful to Professor Ansbacher for his insightful comments on our study of the

appearance of the ossification centers during the third trimester. He is, of course, correct when he points out that traditionally there appear to be gender and race differences in fetal development. However, such findings were based on examinations by use of x-ray film. As the correspondent's references indicate, these examinations were of newborns.

Our methodology, on the other hand, was based on the use of high-resolution ultrasonographic technology and antepartum measurements. We attempted to determine fetal maturity on the basis of nonbiometric measurements. Previous investigators found no differentiation by race in the appearance of the proximal tibial and distal femoral ossification centers.[1] The purpose of our study was to measure the distal femoral and the proximal tibial ossification centers in the axial plane (medial lateral to the epiphysis) to maximize precision and minimize observer variation.

In addition to the ossification centers, there are other parameters that are indicative of fetal maturity. For example, echogenicity of the colon and peristalsis of the small intestine are useful in the prediction of gestational age.[2] Characterization of the nonbiometric measurement can improve the estimation of gestational age during the third trimester and it is advisable to use such assessments for clinical purposes.

Candida warrants concern

To the Editors:

I would like to make a couple of comments concerning an article by Smith et al. (Intraamniotic infection with *Candida albicans* associated with a retained intrauterine contraceptive device: A case report. Am J Obstet Gynecol 1988;159:123-4). Their case report represents the usual reaction by clinicians who perform amniocentesis and find supposedly low virulence organisms that were unexpected. Our natural bias is that these organisms cannot be pathogenic and we tend to minimize their significance. This case, in which *Candida* was discovered at genetic amniocentesis, is an extension of data published by Bruner et al.[1] in which six cases of *Candida* chorioamnionitis diagnosed by amniocentesis were published.

Candida infection in those patients (three of six) was associated with an intrauterine contraceptive device as was the patient in the Smith et al. case report. *Candida* certainly is capable of crossing intact fetal membranes and causing intrauterine infection with potentially catastrophic consequences for the neonate. This case extends the data that we reported and confirms that *Candida albicans* can cause significant intrauterine infection and that perhaps a foreign body such as a retained intrauterine contraceptive device or cerclage may be key to the pathogenesis of this infection.

It is important for clinicians to realize that if *Candida* is discovered at the time of amniocentesis this represents a significant isolate and should be treated with the same concern that would be given to a bacterial isolate from amniotic fluid, either in early gestation or at the time of fetal viability.

Reply

To the Editors:

We greatly appreciate Dr. Elliott's interest in our case report and respond to his comments. At the time of our case report we were unaware of his and Dr. Bruner's extensive experience with *Candida* chorioamnionitis. After review of our case report and the expanding experience with this particular diagnosis we would agree that the appearance of *Candida albicans* on an amniocentesis specimen should be viewed with the same concern as any other bacterial isolate. It is our hope that this case report will inform clinicians of the rare but potentially serious complications associated with intrauterine contraceptive device and pregnancy outcome.

KNOXVILLE, TENNESSEE 37920
EEO/An Affirmative Action/Title IX/Section 504 Employer

CHIEF OF MATERNAL FETAL MEDICINE UNIVERSITY OF TEXAS MEDICAL BRANCH AT GALVESTON

Faculty position in the Division of Maternal-Fetal Medicine in the Department of Obstetrics and Gynecology at the University of Texas Medical Branch at Galveston. A highly qualified individual is sought to become the Chief of the Maternal Fetal Medicine Division. Successful candidates should be board certified or eligible in maternal fetal medicine. They should have a proven record of research and commitment to an academic career. Academic rank is commensurate with qualification and experience. Interested candidates please send curriculum vitae to Garland D. Anderson, M.D., Professor and Chairman, Department of Obstetrics and Gynecology, University of Texas Medical Branch at Galveston, Galveston, Texas 77550.

UTMB is an equal opportunity M/F/H/V Affirmative Action employer. UTMB hires only individuals authorized to work in the United States.

Request for Participation in Maternal Autoimmune Thrombocytopenia Study

We have plans for a treatment study of Maternal Autoimmune Thrombocytopenia. Intravenous Gamma Globulin will be given at 32 + 37 weeks of pregnancy. This will be compared to a similar group receiving no gamma globulin. This study will be done on a randomized basis. History of well documented autoimmune thrombocytopenia prior to present pregnancy will be required for patient entry. Other therapy (steroids, C-section, treatment of infant) will be at local option. We are looking for 10+ centers to participate in such a study. Each center should be able to enroll 5 patients or more for 1 year. If interested in receiving protocol and specifics, please write Dr. William Krivit, Professor of Pediatrics, University of Minnesota Department of Pediatrics, 1252 Ingerson Road, St. Paul, MN 55112.

Immediate Opening
ASSISTANT OR ASSOCIATE PROFESSOR
MATERNAL-FETAL MEDICINE

The Department of Obstetrics & Gynecology, MacDonald Hospital for Women, University Hospitals of Cleveland, and Department of Reproductive Biology, Case Western Reserve University, is actively recruiting two full-time Perinatologists for its Division of Maternal-Fetal Medicine. The department of OB-GYN delivers approximately 3,000 infants per year, with a large number of high risk referrals.

Excellent opportunity to be involved in teaching, ultrasound and prenatal diagnosis including CVS, PUBS, and Fetal Echocardiography. Clinical and basic research are encouraged. There is a Board approved fellowship program. Board eligibility or certification in Maternal-Fetal Medicine is required. Interested candidates should send curriculum vitae to:

J. C. Veille, M.D.
Director, Maternal-Fetal Medicine
Department of Obstetrics & Gynecology
MacDonald Hospital for Women
University Hospitals of Cleveland
2074 Abington Road
Cleveland, OH 44106
Phone: 216-844-3338

The University is an equal opportunity/affirmative action employer.

MATERNAL-FETAL MEDICINE FACULTY POSITION

The Department of Obstetrics and Gynecology, University of Florida College of Medicine, under the direction of Byron J. Masterson, M.D., Professor and Chairman, is seeking applicants for one full-time, tenure accruing faculty position with the rank of Assistant Professor, Associate Professor or Professor for the Division of Maternal-Fetal Medicine.

Board eligibility or certification in maternal-fetal medicine is required. Appointment is contingent upon having a current Florida medical license.

Salary and rank commensurate with training and experience. Application deadline: 9/15/89. Anticipated starting date: 7/1/90.

Send curriculum vitae to:
Amelia C. Cruz, M.D.
Department of Obstetrics and Gynecology
J-294 JHMHC
University of Florida College of Medicine
Gainesville, Florida 32610

"An equal employment opportunity/affirmative action employer"

Obstetrician-gynecologist wanted to join a progressive and prosperous group. Outstanding opportunity for a well trained, board-eligible OB-GYN physician. This practice is strong in high-risk obstetrics, infertility, etc. Working out of a level III hospital. Send CV to:

Drs. Trabin, Manko, and Litt

CHIEF OF OB/GYN
BALTIMORE, MARYLAND

The Johns Hopkins Health Plan is recruiting a Chief for its OB/GYN Department consisting of six physicians and two midwives. Position involves recruiting, utilization review and quality assurance in addition to an active clinical practice in OB/GYN.

The Health Plan is affiliated with The Johns Hopkins School of Medicine and the succesful candidate will receive a clinical faculty appointment and have the opportunity for some teaching. We offer a competitive salary and comprehensive benefits, including paid malpractice.

Interested candidates should reply to: Medical Affairs, The Johns Hopkins Health Plan, 1000 E. Eager Street, Baltimore, MD 21202.

SPECIAL DELIVERIES. SPECIAL CHALLENGES.

The Southern California Permanente Medical Group invites you to join a unique prepaid health care program. Our multispecialty group practice is a partnership composed of and managed by SCPMG physicians.

Board eligible/certified **PERINATOLOGISTS** are needed for our high-volume obstetric services which handles 3,000-6,000 deliveries per year. Opportunities exist both to join and create high risk services.

There are positions available to practice Perinatology exclusively. Perinatologists who are interested in performing other aspects of obstetrics and gynecology may do so. We also have positions available for Endocrinologists and General Obstetrician-Gynecologists. University affiliation and clinical research are encouraged.

Our compensation is competitive and benefits are outstanding. They include: professional liability, medical and dental coverage, vacation and sick leave, continuing education, life insurance and retirement plans. **After two years full-time employment, physicians are eligible to be considered for partnership.**

For a physician application, please call or write to: William G. McCormick, M.D., Physician Recruitment, Dept. 006, Walnut Center, Pasadena, CA 91188-8013. (714) 829-5365.

The Obstetrics and Gynecology Review Course

*November 27-December 6, 1989 — Chicago
Spring 1990 — Site to be Chosen

Now, your comprehensive review of basic and clinical science

OBJECTIVES:
- Increase basic knowledge and clinical skills in ob-gyn.
- Assist residents and fellows to organize study
- Prepare candidates to enter their specialty
- Provide practicing gynecologists with an update

METHODS:
- HOME STUDY MATERIALS with questions and answers
- SEMINAR with projection slides and syllabus
- LABORATORY with microscopic slides
- PRACTICE EXAMS with oral and written parts

*Any six days will complete the program. 8:00 AM to 9:30 PM Nov. 27-Dec. 2 (live); Dec. 3-6 (Video replay of Nov. 27-30).

*"The faculty was outstanding. The most pleasant thing was learning a tremendous amount, not only from world-famous authorities but from people who are relatively unknown as well."**

21- and 28-day regimens

ORTHO-NOVUM® 777 Tablets

norethindrone/ethinyl estradiol

Each white tablet contains 0.5 mg norethindrone and 0.035 mg ethinyl estradiol. Each light peach tablet contains 0.75 mg norethindrone and 0.035 mg ethinyl estradiol. Each peach tablet contains 1 mg norethindrone and 0.035 mg ethinyl estradiol. Each green tablet in 28-day regimen contains inert ingredients.

IMPORTANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information provided with the product and therefore should not be used as the basis for prescribing the product. This summary was prepared by deleting from the complete prescribing information certain text, tables and references. The physician should be thoroughly familiar with the complete prescribing information before prescribing the product.

INDICATIONS AND USAGE: PREVENTION OF PREGNANCY.

CONTRAINDICATIONS: Oral contraceptives should not be used in women who currently have the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophlebitis or thromboembolic disorders. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected carcinoma of the breast. 5. Carcinoma of the endometrium or other known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Cholestatic jaundice of pregnancy or jaundice with prior pill use. 8. Hepatic adenomas or carcinomas. 9. Known or suspected pregnancy.

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia, and gallbladder disease, although the risk of serious morbidity or mortality is very small in healthy women without underlying risk factors. The risk of morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemias, obesity and diabetes. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks. The information contained in this brief summary is principally based on studies carried out in patients who used oral contraceptives with higher formulations of estrogens and progestogens than those in common use today. The effect of long term use of the oral contraceptives with lower formulations of both estrogens and progestogens remains to be determined. Throughout this brief summary epidemiological studies reported are of two types: retrospective or case control studies and prospective or cohort studies. Case control studies provide a measure of the relative risk of a disease, namely a *ratio* of the incidence of a disease among oral contraceptive users to that among nonusers. The relative risk does not provide information on the actual clinical occurrence of a disease. Cohort studies provide a measure of attributable risk, which is the *difference* in the incidence of disease between oral contraceptive users and nonusers. The attributable risk does provide information about the actual occurrence of a disease in the population. For further information, the reader is referred to a text on epidemiological methods. 1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS. a. Myocardial Infarction. An increased risk of myocardial infarction has been associated with oral contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary artery disease such as hypertension, hypercholesterolemia, morbid obesity, and diabetes. The relative risk of heart attack for current oral contraceptive users has been estimated to be two to six. The risk is very low under the age of 30. Smoking in combination with oral contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women in their mid-thirties or older with smoking accounting for the majority of excess cases. Mortality rates associated with circulatory disease have been shown to increase substantially in smokers, especially in those 36 years of age and older among women who use oral contraceptives. Oral contraceptives may compound the effects of well-known risk factors, such as hypertension, diabetes, hyperlipidemias, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and cause glucose intolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see section 9 in WARNINGS). Similar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors. b. Thromboembolism. An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to non-users to be 3 for the first episode of superficial venous thrombosis, 4 to 11 for deep vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboembolic disease. Cohort studies have shown the relative risk to be somewhat lower, about 3 for new cases and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease associated with oral contraceptives is not related to length of use and disappears after pill use is stopped. A two- to four-fold increase in relative risk of post-operative thromboembolic complications has been reported with the use of oral contraceptives. The relative risk of venous thrombosis in women who have predisposing conditions is twice that of women without such medical conditions. If feasible, oral contraceptives should be discontinued at least four weeks prior to and for two weeks after elective surgery of a type associated with an increase in risk of thromboembolism and during and following prolonged immobilization. Since the immediate postpartum period is also associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than four weeks after delivery in women who elect not to breast feed. c. Cerebrovascular diseases. Oral contraceptives have been shown to increase both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes), although, in general, the risk is greatest among older (>35 years), hypertensive women who also smoke. Hypertension was found to be a risk factor for both users and non-users, for both types of strokes, and smoking interacted to increase the risk of stroke. In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for nonsmokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hypertension. The attributable risk is also greater in older women. d. Dose-related risk of vascular disease from oral contraceptives. A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high density lipoproteins (HDL) has been reported with many progestational agents. A decline in serum high density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the activity of the progestogen used in the contraceptive. The activity and amount of both hormones should be considered in the choice of an oral contraceptive. Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For any particular estrogen/progestogen combination, the dosage regimen prescribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral contraceptive agents should be started on preparations containing 0.035 mg or less of estrogen. e. Persistence of risk of vascular disease. There are two studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for at least 9 years for women 40-49 years who had used oral contraceptives for five or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of oral contraceptives, although excess risk was very small. However, both studies were performed with oral contraceptive formulations containing 50 micrograms or higher of estrogens. 2. ESTIMATES OF MORTALITY FROM CONTRACEPTIVE USE. One study gathered data from a variety of sources which have estimated the mortality rate associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific benefits and risks. The study concluded that with the exception of oral contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is low and below that associated with childbirth. However, smokers 35 and older and non-smokers 40 and older who use oral contraceptives have a significant increase in mortality higher than those using other methods of birth control. These facts must be weighed in conjunction with failure rates for other methods and the risk associated with subsequent pregnancy. 3. CARCINOMA OF THE REPRODUCTIVE ORGANS. Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical cancer in women using oral contraceptives. While there are conflicting reports the overall evidence in the literature suggests that use of oral contraceptives is not associated with an increase in the risk of developing breast cancer. The Cancer and Steroid Hormone (CASH) study also showed no latent effect on the risk of breast cancer for at least a decade following long term use. Some studies have shown a slightly increased relative risk of developing breast cancer. Some studies suggest that oral contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors. In spite of many studies of the relationship between oral contraceptive use and breast and cervical cancers, a cause and effect relationship has not been established. 4. HEPATIC NEOPLASIA. Benign hepatic adenomas are associated with oral contraceptive use, although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases/100,000 for users, a risk that increases after four or more years of use especially with oral contraceptives of higher dose. Rupture of benign hepatic adenomas may cause death through intra-abdominal hemorrhage. Studies from Britain have shown an increased risk of developing hepatocellular carcinoma in long-term (>8 years) oral contraceptive users. However, these cancers are rare in the U.S. and the attributable risk (the excess incidence) of liver cancers in oral contraceptive users approaches less than one per million users. 5. OCULAR LESIONS. There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately. 6. ORAL CONTRACEPTIVE USE BEFORE OR DURING EARLY PREGNANCY. RISK OF BIRTH DEFECTS. Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. The majority of recent studies also do not indicate a teratogenic effect, particularly in so far as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently during early pregnancy. The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion. It is recommended that for any patient who has missed two consecutive periods pregnancy should be ruled out before continuing oral contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral contraceptive use should be discontinued until pregnancy is ruled out. 7. GALLBLADDER DISEASE. Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral contraceptive formulations containing lower hormonal doses of estrogens and progestogens. 8. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. Oral contraceptives have been shown to cause a decrease in glucose tolerance in a significant percentage of users. This effect has been shown to be directly related to estrogen dose. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the non-diabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects prediabetic and diabetic women in particular should be carefully monitored while taking oral contraceptives. A small proportion of women will have persistent hypertriglyceridemia while on the pill. As discussed earlier (see WARNINGS 1a and 1d), changes in serum triglycerides and lipoprotein levels have been reported in oral contraceptive users. 9. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in women taking oral contraceptives, and this increase is more likely in older oral contraceptive users and with extended duration of use. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing progestational activity. Women with a history of hypertension or hypertension-related diseases, or renal disease, should be encouraged to use another method of contraception. If women elect to use oral contraceptives, they should be monitored closely and if significant elevation of blood pressure occurs, oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives, and there is no difference in the occurrence of hypertension between former and never users. 10. HEADACHE. The onset or exacerbation of migraine or development of headache with a new pattern which is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause. 11. BLEEDING IRREGULARITIES. Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first three months of use. Non-hormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out. Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was preexistent. 12. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. **PRECAUTIONS:** 1. PHYSICAL EXAMINATION AND FOLLOW UP. A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology, and relevant laboratory tests. In case of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care. 2. LIPID DISORDERS. Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult. 3. LIVER FUNCTION. If jaundice develops in any woman receiving such drugs, the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function. 4. FLUID RETENTION. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention. 5. EMOTIONAL DISORDERS. Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. 6. CONTACT LENSES. Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist. 7. DRUG INTERACTIONS. Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifampin. A similar association, though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines. 8. INTERACTIONS WITH LABORATORY TESTS. Certain endocrine and liver function tests and blood components may be affected by oral contraceptives: a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. b. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radio-immunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. c. Other binding proteins may be elevated in serum. d. Sex-binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids; however, free or biologically active levels remain unchanged. e. Triglycerides may be increased. f. Glucose tolerance may be decreased. g. Serum folate levels may be depressed by oral contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives. 9. CARCINOGENESIS. See WARNINGS section. 10. PREGNANCY. Pregnancy Category X. See CONTRAINDICATIONS and WARNINGS sections. 11. NURSING MOTHERS. Small amounts of oral contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child. **INFORMATION FOR THE PATIENT: See Patient Package Insert. ADVERSE REACTIONS:** An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS section): Thrombophlebitis and venous thrombosis with or without embolism. Arterial thromboembolism. Pulmonary embolism. Myocardial infarction. Cerebral hemorrhage. Cerebral thrombosis. Hypertension. Gallbladder disease. Hepatic adenomas or benign liver tumors. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea. Vomiting. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Amenorrhea. Temporary infertility after discontinuation of treatment. Edema. Melasma which may persist. Breast changes: tenderness, enlargement, secretion. Change in weight (increase or decrease). Change in cervical erosion and secretion. Diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted: Pre-menstrual syndrome. Cataracts. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiforme. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. Hemolytic uremic syndrome. Acne. Changes in libido. Colitis. **OVERDOSAGE:** Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea and withdrawal bleeding may occur in females.

Revised 11/88

ORTHO PHARMACEUTICAL CORPORATION
Raritan, NJ 08869-0602

ORTHO

Low rates of breakthrough bleeding and nuisance side effects†

High levels of patient satisfaction

21- and 28-day regimens

ORTHO-NOVUM® 777 Tablets

norethindrone/ethinyl estradiol

†Serious as well as minor side effects have been reported with the use of oral contraceptives. The physician should remain alert to the earliest manifestations of any symptoms of serious disease and discontinue oral contraceptive therapy when appropriate.

Please see brief summary of complete Prescribing Information on the preceding page.

Even at midcycle, she wears white with confidence

Only Tri-Norinyl provides a full 1 mg of progestin at the midcycle (days 8–16), when clinical data indicate that breakthrough bleeding and spotting are most likely to occur.[1]

To help control midcycle breakthrough bleeding: make the midcycle the high point of protection.

Extra midcycle progestin to reduce midcycle breakthrough bleeding

9 DAYS
1.0 mg norethindrone

7 DAYS
0.5 mg norethindrone

5 DAYS
0.5 mg norethindrone

21 DAYS *0.035 mg ethinyl estradiol*

TRI-NORINYL®

(NORETHINDRONE AND ETHINYL ESTRADIOL) TABLETS

1. Data available from Syntex Laboratories, Inc., document #92363.

Serious as well as minor side effects have been reported following the use of all oral contraceptives. These include thromboembolic disease. Before prescribing Tri-Norinyl, please see brief summary of prescribing information on following page.

TRI-NORINYL®

(NORETHINDRONE AND ETHINYL ESTRADIOL) TABLETS

TRI-NORINYL® 21-Day Tablets (7 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 9 green tablets of norethindrone 1.0 mg with ethinyl estradiol 0.035 mg, 5 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg)
TRI-NORINYL® 28-Day Tablets (7 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 9 green tablets of norethindrone 1.0 mg with ethinyl estradiol 0.035 mg, 5 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg; 7 inert tablets)
BREVICON® 21-Day Tablets (norethindrone 0.5 mg with ethinyl estradiol 0.035 mg)
BREVICON® 28-Day Tablets (21 norethindrone 0.5 mg with ethinyl estradiol 0.035 mg tablets followed by 7 inert tablets)
NORINYL® 1 + 35 21-Day Tablets (norethindrone 1 mg with ethinyl estradiol 0.035 mg)
NORINYL® 1 + 35 28-Day Tablets (21 norethindrone 1 mg with ethinyl estradiol 0.035 mg tablets followed by 7 inert tablets)
NORINYL® 1 + 50 21-Day Tablets (norethindrone 1 mg with mestranol 0.05 mg)
NORINYL® 1 + 50 28-Day Tablets (21 norethindrone 1 mg with mestranol 0.05 mg tablets followed by 7 inert tablets)
NORINYL® 1 + 80 21-Day Tablets (norethindrone 1 mg with mestranol 0.08 mg)
NORINYL® 1 + 80 28-Day Tablets (21 norethindrone 1 mg with mestranol 0.08 mg tablets followed by 7 inert tablets)
NORINYL® 2 mg Tablets (norethindrone 2 mg with mestranol 0.1 mg)
NOR-Q.D.® (norethindrone) Tablets 0.35 mg

ORAL CONTRACEPTIVE (O.C.) AGENTS

Indications Prevention of pregnancy. *DOSE-RELATED RISK OF THROMBOEMBOLISM.* Because studies have shown a positive association between OC estrogen dose and risk of thromboembolism, it is prudent to minimize estrogen exposure. Prescribe an OC with the least amount of estrogen compatible with an acceptable pregnancy rate and patient acceptance. Start new users on OCs containing 0.05 mg or less of estrogen.

Contraindications 1. Known or suspected pregnancy (see Warning #5). 2. Thrombophlebitis or thromboembolic disorders. 3. Past history of deep vein thrombophlebitis or thromboembolic disorders. 4. Undiagnosed abnormal genital bleeding. 5. OCs should not be used by women who have or have had any of the following: a. cerebral vascular or coronary artery disease, including myocardial infarction. b. known or suspected carcinoma of the breast. c. known or suspected estrogen dependent neoplasia. d. benign or malignant liver tumor that developed during use of OCs or other estrogen containing products.

WARNINGS: Cigarette smoking increases the risk of serious cardiovascular side effects from OC use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use OCs should be strongly advised not to smoke.

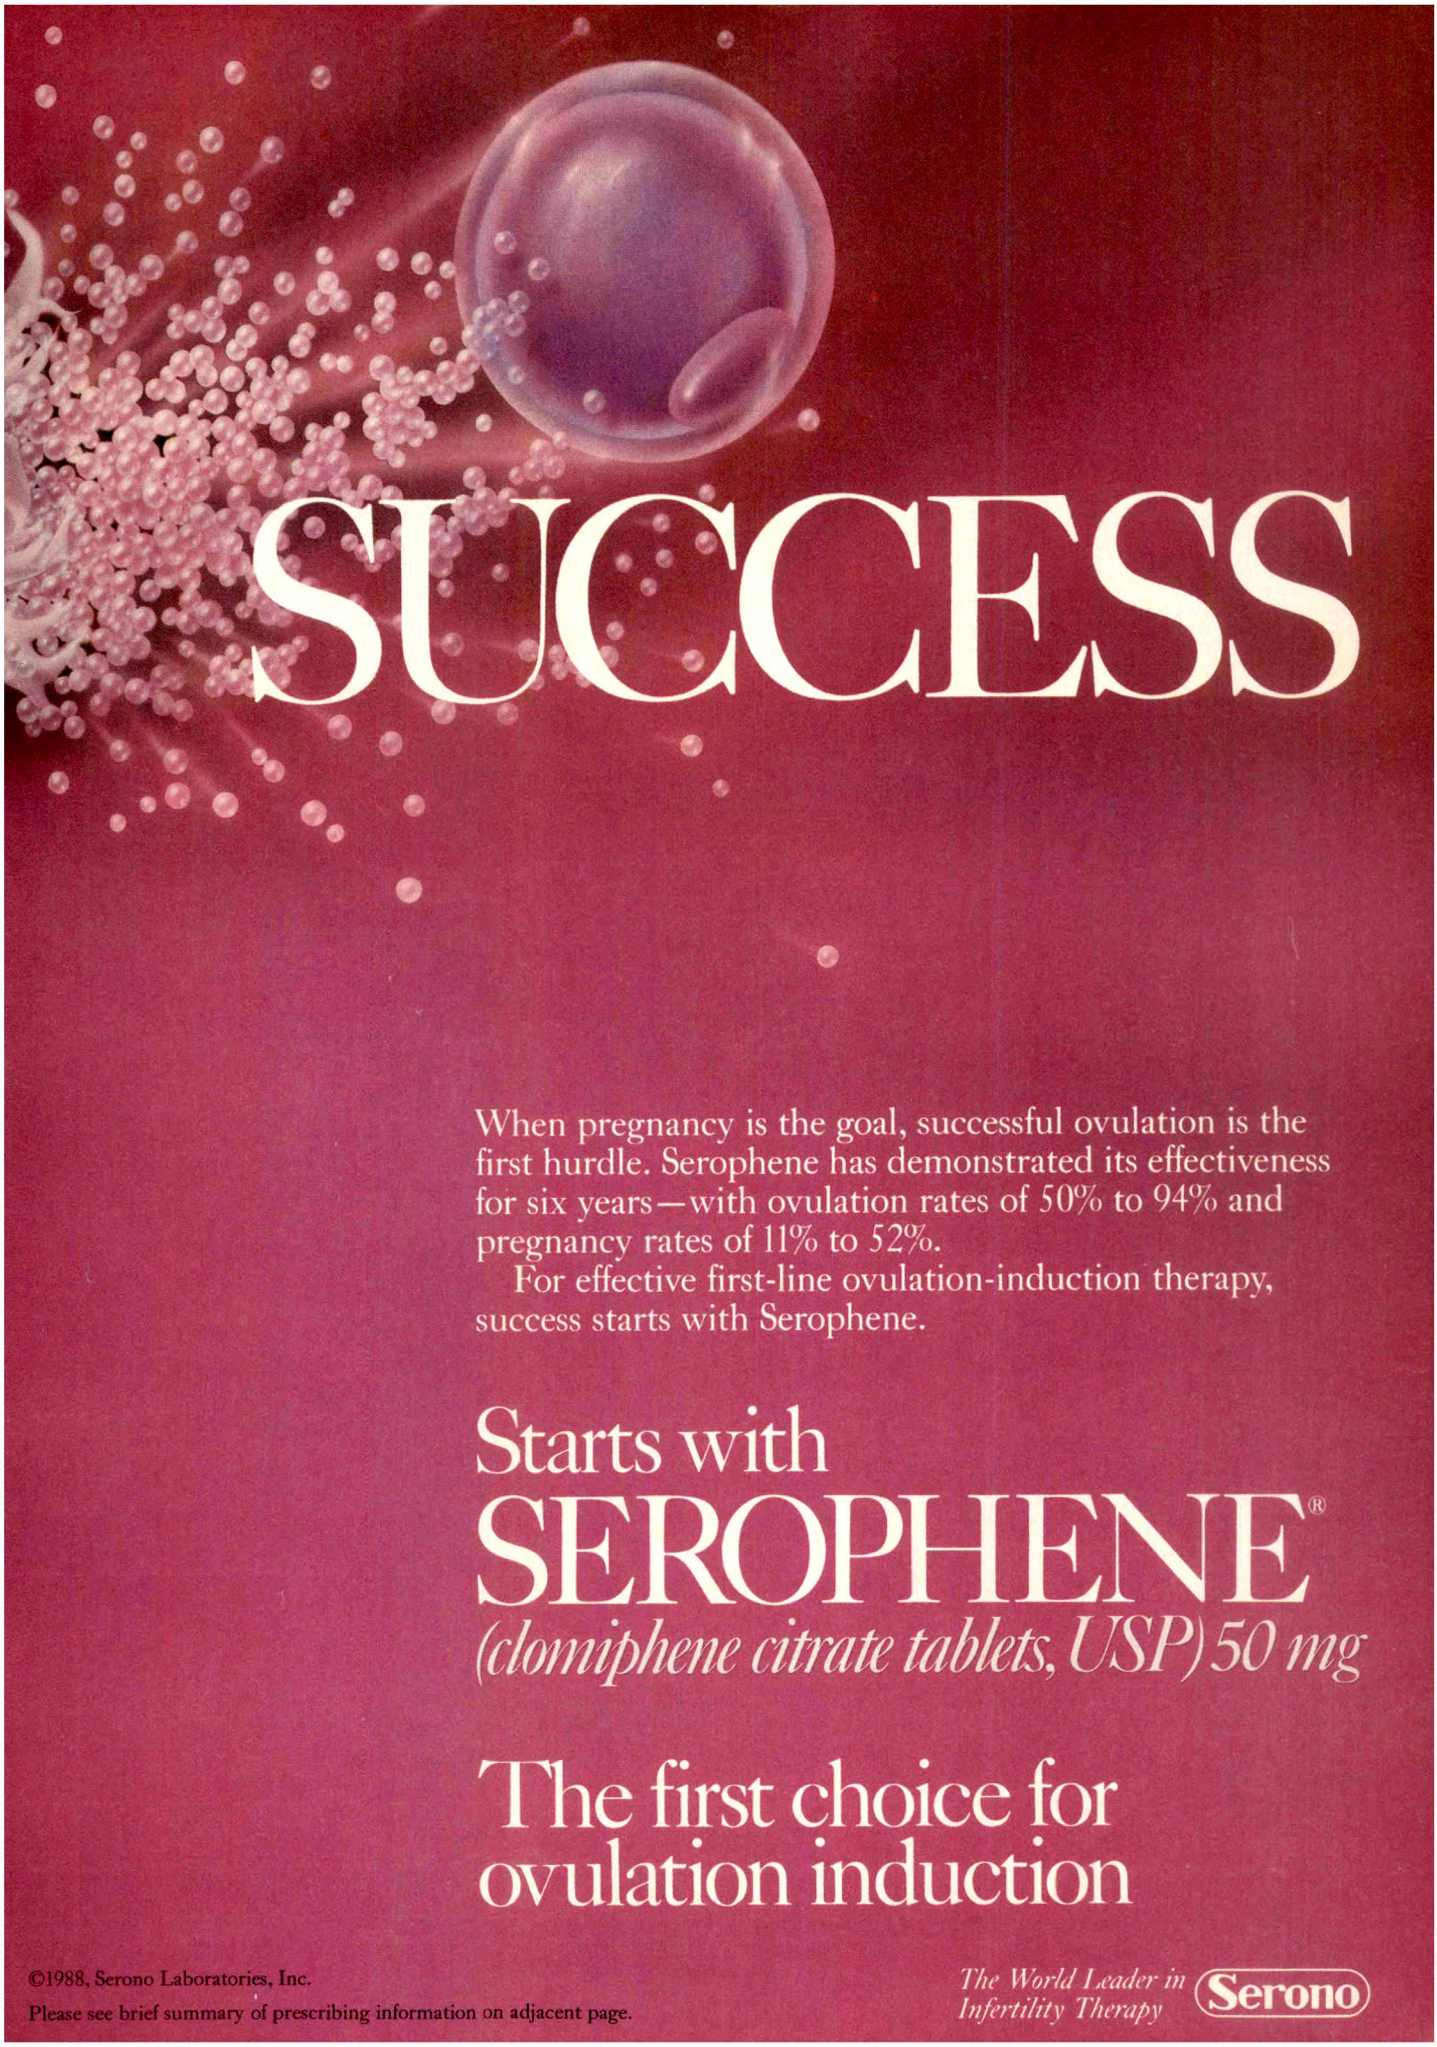
The use of OCs is associated with increased risk of several serious conditions including thromboembolism, stroke, myocardial infarction, liver tumor, gall bladder disease, visual disturbances, fetal abnormalities, and hypertension. Practitioners prescribing OCs should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with OC use is established. One study demonstrated an increased relative risk for fatal venous thromboembolism and several studies demonstrated it for non-fatal venous thromboembolism. They estimate that OC users are 4-11 times more likely than nonusers to develop these diseases without evident cause. One British study reported an excess death rate of 40% in OC users, most of which resulted from cardiovascular disease. Another British study showed a lower death rate in OC users than controls; an increase in cardiovascular deaths was seen but was not statistically significant. A U.S. prospective study failed to disclose increased mortality rates from cardiovascular disorders, but a subset analyzed as a retrospective, case-control study showed significant increases in venous thromboembolism. CEREBROVASCULAR DISORDERS. Two American studies demonstrated an increased relative risk for stroke not shown in prior British studies. In an American study of cerebrovascular disorders in women with and without predisposing causes, relative risk of hemorrhagic stroke was estimated as 2.0 times greater and thrombotic stroke as 4-9.5 times greater in users than nonusers. A British long-term follow-up study reported in 1976 a highly significant association between OC use and stroke. Another study had suggested an association in 1974, but the number of cases was too small to estimate the risk. Subarachnoid hemorrhage has been shown to be increased by OC use in British and American studies. Smoking alone increases incidence of these accidents; smoking and pill use appear to increase risk more than either alone.

MYOCARDIAL INFARCTION (MI). Increased relative risk of MI associated with OC use has been reported. One British study found that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing MI, regardless of OC use. OCs were an additional risk factor. In terms of relative risk, it has been estimated that nonsmoking OC users (smoking is considered a major predisposing condition to MI) are twice as likely to have a fatal MI as nonsmoking nonusers. OC users who are smokers have a 5-fold increased risk of fatal infarction compared to nonsmoking users, and a 10-12-fold increased risk compared to nonsmoking nonusers. The number of cigarettes smoked is important. In determining the importance of these relative risks, baseline rates for various age groups must be considered. (Estimates are based on British vital statistics which show acute MI death rates 2-3 times less than in the U.S. so U.S. death rates could be higher.) Importance of other predisposing conditions in determining relative and absolute risks has not been quantified; other synergistic actions may exist. RISK OF DOSE. Using data from several national adverse reaction reporting systems, British investigators concluded that risk of thromboembolism, including coronary thrombosis, is directly related to estrogen dose in OCs. OCs with 0.1 mg or more of estrogen were associated with a higher risk of thromboembolism than those containing 0.05-0.08 mg but quantity of estrogen may not be the sole factor. This was supported by a U.S. study. A British study found a positive association between dose of progestogen or estrogen and certain thromboembolic conditions. Swedish authorities noted decreased reporting of thromboembolic episodes when higher estrogen preparations were no longer prescribed. Careful epidemiological studies to determine degree of thromboembolic disease risk associated with progestogen-only OCs have not been done. Thromboembolic disease has been reported in women using these products, and they should not be considered free of excess risk. PERSISTENCE OF RISK. Two studies have suggested an increased risk may persist for 6 years after discontinuation of OC use for cerebrovascular disease and 9 years for MI; another study suggested the persistence of risk for subarachnoid hemorrhage. ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES. A large British prospective study estimated mortality rate per 100,000 women per year from circulatory system diseases for OC users and nonusers according to age, smoking habits, and duration of use. The overall annual excess death rate for OC users was estimated to be 20/100,000 (ages 15-34–5/100,000; ages 35-44–33/100,000; ages 45-49–140/100,000). Risk is concentrated in long-term users and in smokers, and may persist after OC discontinuation. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all occurred in women 35 or older. An update provided the following rates: ages 15-34–1/6700 for nonsmokers and 1/2000 for smokers; ages 45 and over–1/2500 for nonsmokers and 1/500 for smokers. Risk appeared to increase with parity, but not with duration of use. Until more women under 35 with continuous use for 5 or more years are available, it is not possible to assess relative risk for this age group. Data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. Estimates include combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease for OCs) plus risk attributable to pregnancy or abortion if the method fails (which varies with the effectiveness of the contraceptive method). The study concluded that mortality associated with all contraceptive methods is below that of childbirth, except for OCs in women over 40 who smoke. (Rates given for pill only/smokers for each age are for smokers as a class. For "heavy" smokers (more than 15 cigarettes a day), the rates would be about double; for "light" smokers (less than 15), about half.) The lowest mortality is with the condom or diaphragm backed up by early abortion. The study also concluded that OC users who smoke, especially over 30, have greater mortality risk than OC users who do not smoke.

Risk of thromboembolic and thrombotic disease associated with OCs increases with age after 30 and for MI is further increased by hypertension, hyperlipidemias, obesity, diabetes, or history of preeclamptic toxemia, and especially by smoking. The following chart gives a gross estimate of risk of death from circulatory disorders associated with OC use.

SMOKING HABITS AND OTHER PREDISPOSING CONDITIONS–RISK ASSOCIATED WITH USE OF OCs



Age	Below 30	30-39	40 +
Heavy smokers	C	B	A
Light smokers	D	C	B
Nonsmokers (no predisposing conditions)	D	C,D	C
Nonsmokers (other predisposing conditions)	C	C,B	B,A

A–Use associated with very high risk.
B–Use associated with high risk.
C–Use associated with moderate risk.
D–Use associated with low risk.

Physician and patient should be alert to earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, discontinue OC immediately. A 4-6 fold increased risk of post-surgery thromboembolic complications has been reported in OC users. If feasible, discontinue OCs at least 4 weeks before surgery associated with increased risk of thromboembolism or prolonged immobilization. Before resuming OC after major surgery or bedrest, balance risks of post-surgery thromboembolic complications with contraceptive needs. Data suggest varicose veins substantially increase risk of superficial venous thrombosis of the leg, the risk depending on the severity of the varicosities. 2. *Ocular Lesions:* Neuro-ocular lesions such as optic neuritis or retinal thrombosis have been associated with OC use. Discontinue OC if there is unexplained, sudden, or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions; and institute appropriate diagnostic and therapeutic measures. 3. *Carcinoma:* Long-term continuous administration of natural or synthetic estrogen in certain animals increases certain tumors, benign or malignant, such as breast, cervix, vagina, uterus, ovary, pituitary and liver. Certain synthetic progestogens, none currently in OCs, increase the incidence of mammary nodules, benign and malignant, in dogs. Several retrospective case-control studies reported an increased relative risk (3.1-13.9 times) associating endometrial carcinoma with the prolonged use of estrogens in postmenopausal women. One publication reported the first 30 cases submitted to the registry of cases of adenocarcinoma of the endometrium in women under 40 on OCs. Of the adenocarcinomas found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding when OCs were first given, polycystic ovaries), nearly all occurred in women who had used sequential OCs, which are no longer marketed. No statistical association has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only OCs, although individual cases have been reported. Studies have shown no increased risk of breast cancer to OC or estrogen users. One study found no overall increased risk of breast cancer in OC users but a greater risk was suggested for OC users with documented benign breast disease and for long-term (2-4 years) users. Another study found a history of breast cancer among grandmothers or aunts was significantly more frequent among breast cancer patients who had used an OC continuously for one or more years than among nonusers with breast cancer. One other study indicated an increasing risk of breast cancer in women taking menopausal estrogens, which increased with duration of follow-up. One author suggests that extended (over 6 years) OC use prior to first full term pregnancy was associated with a significant relative risk of breast cancer, and other studies suggested an increased risk of breast cancer with long-term OC use before age 25. A reduced occurrence of benign breast tumors in OC users has been well documented. One study reported malignant melanoma more frequently in OC users than controls and suggests an increased incidence of urinary tract and thyroid cancers. A prospective study of women with cervical dysplasia found an increase in severity and conversion to cancer *in situ* in OC users compared to nonusers. This became statistically significant after 3-4 years of use. Nonreversal of dysplasia within the first 6 months of pill use was suggested to predict progression after prolonged exposure. One study disclosed an increased risk of cancer of the cervix (largely carcinoma *in situ*) in OC users under 40, particularly those who had used OCs over 4 years. Two other studies suggested an increasing incidence of cervical neoplasms with longer duration of OC use. There have been other reports of microglandular hyperplasia of the cervix in OC users. One study reported an association between OC use and endocervical adenocarcinoma. In summary, there is no confirmed evidence from human studies of increased risk of cancer associated with OCs. Close clinical surveillance of all OC users is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, take appropriate diagnostic measures to rule out malignancy. Monitor OC users with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms with particular care. (See also Warnings, 4. *Liver Tumors.*) 4. *Liver Tumors:* Sudden severe abdominal pain or shock may be due to rupture and hemorrhage of a liver tumor. There have been reports associating benign or malignant liver tumors with short-term and long-term OC use. One study reported use of OCs with high hormonal potency and age over 30 may further increase risk of hepatocellular adenoma. Two studies relate risk with duration of use, risk being much greater after 4 or more years of use. Long-term OC users have an estimated annual incidence of hepatocellular adenoma of 3-4/100,000. Although an uncommon lesion, it should be considered in women presenting with an "acute abdomen". The tumor may cause serious or fatal hemorrhage. Patients with liver tumors have demonstrated variable clinical features which may make preoperative diagnosis difficult. Some cases presented because of right upper quadrant masses, while most had signs and symptoms of acute intraperitoneal hemorrhage. Routine radiological and laboratory studies may not be helpful. Liver scans may show a focal defect. Hepatic arteriography may be useful in diagnosing primary liver neoplasm. Cases of hepatocellular carcinoma have been reported in long-term users of OCs.[65-167] An epidemiological study suggested a 4-fold increase in relative risk for hepatocellular carcinoma in OC users for 8 years or more, which increased to 7 in women with markers of hepatitis B. A second study suggested a risk of about 20 for use in excess of 8 years. 5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring, and Malignancy in Female Offspring:* Use of female sex hormones–estrogenic and progestational agents–during early pregnancy may seriously damage the offspring. Females exposed *in utero* to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1/1000 exposures or less. Although there is no evidence that OCs further enhance the risk of developing this type of malignancy, such OC users should be monitored with particular care. A high percentage of women exposed to diethylstilbestrol (30-90%) have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are a precursor of vaginal malignancy. Male children so exposed may develop urogenital tract abnormalities. Although similar data are not available on other estrogens, it cannot be presumed that they would not induce similar changes. Increased risk of congenital anomalies, including heart and limb defects, has been reported following use of sex hormones, including OCs, in pregnancy. One case-control study estimated a 4.7-fold increased relative risk of limb-reduction defects in infants exposed *in utero* to sex hormones (OCs, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some exposures involved only a few days of treatment. Data suggest risk of limb-reduction defects in exposed fetuses is somewhat less than 1/1000 live births. In a large prospective study, cardiovascular defects in children born to women who received female hormones, including OCs, during early pregnancy occurred at 18.2/1000 births, compared to 7.8/1000 for children not so exposed *in utero.* These results are statistically significant. A Welsh study found a statistically significant excess of neural tube defects among offspring of prior OC users (within 3 months) than among controls. The incidence of twin births may be increased for women who conceive shortly after discontinuing OC use. In the past, female sex hormones were used during pregnancy in an attempt to treat threatened or habitual abortion. There is evidence that estrogens are ineffective, and there is no evidence from well controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OCs. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OCs is unknown. If the patient has not adhered to the prescribed schedule, consider possible pregnancy at the first missed period (or 45 days from the last menstrual period if progestogen-only OCs are used) and discontinue OC use until pregnancy has been ruled out. For any patient who has missed two consecutive periods, rule out pregnancy before continuing the OC. If pregnancy is confirmed, tell the patient about potential risks to the fetus and discuss advisability of continuing the pregnancy. Women who discontinue OCs to become pregnant should use an alternate form of contraception for a period of time before attempting to conceive. A 3-month period is supported by a study suggesting increased frequency of neural tube defects in women impregnated during the first 3 months after cessation of OC use. Do not use progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding as a pregnancy test. 6. *Gall Bladder Disease:* Studies report increased risk of gall bladder disease in OC or estrogen users. In one study, an increased risk appeared after 2 years of use and doubled after 4-5 years. In another study, an increased risk was apparent between 6 and 12 months. 7. *Carbohydrate and Lipid Metabolic Effects:* Because a decrease in glucose tolerance has been observed in a significant percentage of patients on OCs, prediabetic and diabetic OC users should be carefully observed. An increase in triglycerides and total phospholipids has been observed in OC users but its clinical significance is unknown. 8. *Elevated Blood Pressure:* An increase in blood pressure has been reported with OC use. Hypertension may occur within a few months of beginning OCs. In the first year of use, incidence of hypertension may be no higher in OC users than in nonusers. Incidence in users increases with exposure and in the fifth year of use is 2.5-3 times that in the first year. Age is strongly correlated with hypertension in OC users. Women with a history of elevated blood pressure (hypertension), preexisting renal disease, history of toxemia or elevated blood pressure during pregnancy, familial tendency to hypertension or its consequences, or history of excessive weight gain or fluid retention during the menstrual cycle may be more likely to develop elevated blood pressure when given OCs and should be monitored closely. Even though elevated blood pressure may remain within the "normal" range, closely watch elevations, particularly for women with other risk factors for cardiovascular disease or stroke. High blood pressure may or may not persist after OC discontinuation. 9. *Headache:* Discontinue OC and evaluate the cause of onset or exacerbation of migraine or development of a new pattern of headache which is recurrent, persistent, or severe. 10. *Bleeding Irregularities:* Breakthrough bleeding, spotting, and missed menses often make users discontinue OCs. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, consider nonfunctional causes. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, use adequate diagnostic measures to rule out pregnancy or malignancy. If pathology has been excluded, time or another formulation may solve the problem. While potentially useful in minimizing menstrual irregularity, change to an OC with a higher estrogen content only if necessary since this may increase the risk of thromboembolic disease. Women with a history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may tend to remain anovulatory or to become amenorrheic after OC discontinuation. Women with these preexisting problems should be advised of this and encouraged to use other contraceptive methods. Post-use anovulation, possibly prolonged, may occur in women without previous irregularities. A higher incidence of galactorrhea and of pituitary tumors (e.g., adenomas) has been associated with amenorrhea in former users compared with nonusers. One study reported a 16-fold increased incidence of pituitary prolactin-secreting tumors among patients with postpill amenorrhea when galactorrhea was present. 11. *Infertility:* There is evidence of impairment of fertility in women discontinuing OCs in comparison with other contraceptive methods, which appears to be independent of duration of use. While impairment diminishes with time, there is an appreciable difference in the results in nulliparous women for OC and other groups 30 months after discontinuation of birth control. For parous women the difference is not apparent 30 months after cessation of contraception. One study suggests that the incidence of *Chlamydia trachomatis* infection, the leading cause of nongonococcal PI.D., is increased by OCs. 12. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in OC failure. In progestogen-only OC failures, the ratio of ectopic to intrauterine pregnancies is higher than in nonusers, since the drugs are more effective in preventing intrauterine than ectopic pregnancies. 13. *Breast Feeding:* OCs in the postpartum period may interfere with lactation by decreasing quantity and quality of breast milk. A small fraction of OC hormonal agents has been identified in milk of mothers receiving OCs. Effects, if any, on the breast-fed child have not been determined. If feasible, defer OC use until the infant has been weaned. **Precautions** *GENERAL* 1. Take a complete medical and family history before starting OCs. Pretreatment and periodic physical exams should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant lab tests. As a general rule, OCs should not be prescribed for longer than 1 year without another physical. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may enlarge. 3. Observe patients with a history of psychic depression and discontinue OCs if depression recurs to a serious degree. Patients becoming significantly depressed while taking OCs should stop the OC and use an alternate method of contraception to determine whether the symptom is drug related. 4. OCs may cause some fluid retention. Prescribe with caution, and only with careful monitoring, in patients with conditions that might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma or cardiac, hepatic or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence while using OCs. Discontinue OC if jaundice develops. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. OC users may have disturbances in normal tryptophan metabolism that may result in a relative pyridoxine deficiency. The clinical significance is unknown. 8. Serum folate levels may be depressed by OC use. Since the pregnant woman is predisposed to folate deficiency and incidence of folate deficiency increases with increasing gestation, if a woman becomes pregnant shortly after stopping OCs, she may have a greater chance of developing folate deficiency and related complications. 9. Advise the pathologist of OC use when relevant specimens are submitted. 10. Certain endocrine and liver function tests and blood components may be affected by estrogen-containing OCs. For example: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test. f. Increased phospholipids and triglycerides. g. Temporarily decreased glucose tolerance. 11. Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist and temporary or permanent cessation of wear considered. DRUG INTERACTIONS. OCs may be less effective and there may be increased breakthrough bleeding from interactions with rifampin, isoniazid, ampicillin, tetracycline, neomycin, penicillin V, chloramphenicol, sulfonamides, nitrofurantoin, barbiturates, phenytoin, primidone, analgesics, tranquilizers, antimigraine preparations, antihistamines, and griseofulvin. OCs may alter effectiveness of such other drugs as oral anticoagulants, anticonvulsants, tricyclic antidepressants, antihypertensive agents (e.g., guanethidine), vitamins, hypoglycemic agents, tranquilizers, hypnotic preparations, theophylline, and beta blockers. Toxic liver effects have been reported with a combination of an OC and cyclosporin A. *CARCINOGENESIS* See Warnings. *PREGNANCY* Pregnancy category X. See Contraindications and Warnings. *NURSING MOTHERS* See Warnings. **Adverse Reactions** An increased risk of the following serious adverse reactions has been associated with OC use (see Warnings): thrombophlebitis, thrombosis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, mesenteric thrombosis, liver tumors, cerebral hemorrhage, hypertension, gall bladder disease, congenital anomalies, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis, Budd-Chiari syndrome, Raynaud's disease, arterial thromboembolism. The following adverse reactions have been reported in OC users and are believed to be drug related: bleeding irregularities (breakthrough bleeding, spotting, missed menses during treatment, amenorrhea after treatment), gastrointestinal symptoms (nausea, vomiting, bloating, abdominal cramps, colitis), dysmenorrhea, infertility after discontinuance of treatment, edema, chloasma or melasma which may persist after drug is discontinued, breast changes (tenderness, enlargement, and secretion), intolerance to contact lenses, changes in corneal curvature (steepening), change in weight (increase or decrease), change in cervical erosion and cervical secretion, possible diminution of lactation when given immediately postpartum, cholestatic jaundice, migraine, increase in size of uterine leiomyomata, rash (allergic), mental depression, reduced tolerance to carbohydrates, vaginal candidiasis, prolactin-secreting pituitary tumors, chilblains. The following adverse reactions have been reported in OC users and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of hair, erythema multiforme, erythema nodosum, hemorrhagic eruptions, vaginitis, porphyria, impaired renal function, malignant nephrosclerosis (hemolytic uremic syndrome), malignant hypertension, acute renal failure, premature supraventricular contractions. **Information for the Patient** (See Patient Package Insert).

Rev. April 1987

SYNTEX

When pregnancy is the goal, successful ovulation is the first hurdle. Serophene has demonstrated its effectiveness for six years—with ovulation rates of 50% to 94% and pregnancy rates of 11% to 52%.

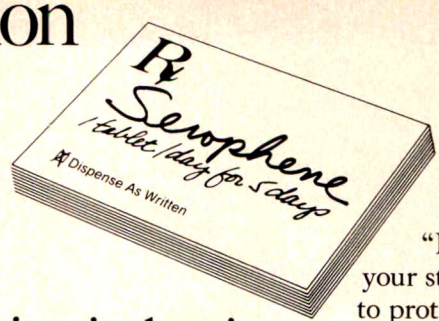
For effective first-line ovulation-induction therapy, success starts with Serophene.

Starts with SEROPHENE®

(clomiphene citrate tablets, USP) 50 mg

The first choice for ovulation induction

©1988, Serono Laboratories, Inc.



Please see brief summary of prescribing information on adjacent page.

The World Leader in Infertility Therapy

Serono

Successful ovulation starts with SEROPHENE®

(clomiphene citrate tablets, USP) 50 mg

Be sure your patients receive the drug you prescribe. Specify "Dispense as Written" or your state's approved wording to protect the integrity of your Serophene prescription.

The first choice for ovulation induction

Serophene®
(clomiphene citrate tablets, USP)
Brief Summary:
Indications:
Clomiphene citrate is indicated for the treatment of ovulatory failure in patients desiring pregnancy, and whose husbands are fertile and potent. Impediments to this goal must be excluded or adequately treated before beginning therapy. Administration of clomiphene citrate is indicated only in patients with demonstrated ovulatory dysfunction and in whom the following conditions apply:

1. Normal liver function.
2. Physiologic indications of normal endogenous estrogen (as estimated from vaginal smears, endometrial biopsy, assay of urinary estrogen, or from bleeding in response to progesterone). Reduced estrogen levels, while less favorable, do not prevent successful therapy.
3. Clomiphene citrate therapy is not effective for those patients with primary pituitary or ovarian failure. It cannot substitute for appropriate therapy of other disturbances leading to ovulatory dysfunction, e.g., diseases of the thyroid or adrenals.
4. Particularly careful evaluation prior to clomiphene citrate therapy should be done in patients with abnormal uterine bleeding. It is most important that neoplastic lesions are detected.

Contraindications:
Pregnancy
Although no direct effect of clomiphene citrate therapy on the human fetus has been seen, clomiphene citrate should not be administered in cases of suspected pregnancy as such effects have been reported in animals. To prevent inadvertent clomiphene citrate administration during early pregnancy, the basal body temperature should be recorded throughout all treatment cycles, and therapy should be discontinued if pregnancy is suspected. If the basal body temperature following clomiphene citrate is biphasic and is not followed by menses, the possibility of an ovarian cyst and/or pregnancy should be excluded. Until the correct diagnosis has been determined, the next course of therapy should be delayed.
Liver Disease
Patients with liver disease or a history of liver dysfunction should not receive clomiphene citrate therapy.
Abnormal Uterine Bleeding
Clomiphene citrate is contraindicated in patients with abnormal uterine bleeding.
Warnings:
Visual Symptoms
Patients should be warned that blurring and/or other visual symptoms may occur occasionally with clomiphene citrate therapy. These may make activities such as driving or operating machinery more hazardous than usual, particularly under conditions of variable lighting. While their significance is not yet understood (see ADVERSE REACTIONS), patients having any visual symptoms, should discontinue treatment and have a complete ophthalmologic evaluation.
Precautions:
Diagnosis Prior to Clomiphene Citrate Therapy
Careful evaluation should be given to candidates for clomiphene citrate therapy. A complete pelvic examination should be performed prior to treatment and repeated before each subsequent course. Clomiphene citrate should not be given to patients with an ovarian cyst, as further ovarian enlargement may result.
Since the incidence of endometrial carcinoma and of ovulatory disorders increases with age, endometrial biopsy should always exclude the former as causative in such patients. If abnormal uterine bleeding is present, full diagnostic measures are necessary.
Ovarian Overstimulation During Treatment with Clomiphene Citrate
To minimize the hazard associated with the occasional abnormal ovarian enlargement during clomiphene citrate therapy (see ADVERSE REACTIONS), the lowest dose producing good results should be chosen. Some patients with polycystic ovary syndrome are unusually sensitive to gonadotropin and may have an exaggerated response to usual doses of clomiphene citrate. Maximal enlargement of the ovary, whether abnormal or physiologic, does not occur until several days after discontinuation of clomiphene citrate. The patient complaining of pelvic pains after receiving clomiphene citrate should be examined carefully. If enlargement of the ovary occurs, clomiphene citrate therapy should be withheld until the ovaries have returned to pretreatment size, and the dosage or duration of the next course should be reduced. The ovarian enlargement and cyst formation following clomiphene citrate therapy regress spontaneously within a few days or weeks after discontinuing treatment. Therefore, unless a strong indication for laparotomy exists, such cystic enlargement always should be managed conservatively.
Multiple Pregnancy
In the reviewed publications, the incidence of multiple pregnancies was increased during those cycles in which clomiphene citrate was given. Among the 1803 pregnancies on which the outcome was reported, 90% were single and 10% twins. Less than 1% of the reported deliveries resulted in triplets or more.
Of these multiple pregnancies, 96-99% resulted in the births of live infants. The patient and her husband should be advised of the frequency and potential hazards of multiple pregnancy before starting treatment.
Adverse Reactions:
Symptoms
Side effects are not prominent at the recommended dosage of clomiphene citrate, and infrequently interfere with treatment. Side effects tend to occur more frequently at higher doses and in the longer treatment courses used in some early studies. The more common side effects and the percent of patients experiencing them include vasomotor flushes (11%), abdominal discomfort (7.4%), abnormal uterine bleeding (0.5%), ovarian enlargement (14%), breast tenderness (2.1%), and visual symptoms (1.6%). The vasomotor symptoms resemble menopausal "hot flushes," and are not usually severe. They promptly disappear after treatment is discontinued. Abdominal discomfort may resemble ovulatory (mittelschmerz) or premenstrual phenomena, or that due to ovarian enlargement. In addition, nausea and vomiting (2.1%), nervousness and insomnia (1.9%), headache (1%), dizziness and lightheadedness (1%), increased urination (0.9%), depression and fatigue (0.8%), urticaria and allergic dermatitis (0.6%), weight gain (0.4%), and reversible hair loss (0.3%) have been reported.
When clomiphene citrate is administered at the recommended dose, abnormal ovarian enlargement (see PRECAUTIONS) is infrequent, although the usual cyclic variation in ovarian size may be exaggerated. Similarly, mid-cycle ovarian pain (mittelschmerz) may be accentuated. With prolonged or higher dosage, ovarian enlargement and cyst formation (usually luteal) may occur more often and the luteal phase of the cycle may be prolonged. Patients with polycystic ovary disease may be unusually sensitive to clomiphene therapy. Rare occurrences of massive ovarian enlargement have been reported, for example, in a patient with polycystic ovary syndrome whose clomiphene citrate therapy consisted of 100 mg daily for 14 days. Since abnormal ovarian enlargement usually regresses spontaneously, most of these patients should be treated conservatively.
The incidence of visual symptoms (see WARNINGS for further recommendations), usually described as "blurring" or spots or flashes (scintillating scotomata), correlates with increasing total dose. The symptoms disappear within a few days or weeks after clomiphene citrate is discontinued. This may be due to intensification and/or prolongation of after-images. Symptoms often appear first, or are accentuated, upon exposure to a more brightly lit environment. While measured visual acuity has not generally been affected, in one patient taking 200 mg daily, visual blurring developed on the seventh day of treatment, and progressed to severe diminution of visual acuity by the tenth day. No other abnormality was coincident, and the visual acuity was normal by the third day after treatment was stopped. Ophthalmologically definable scotomata and electroretinographic retinal function changes have also been reported.
BSP Laboratory Studies
Greater than 5% retention of sulfobromophthalein (BSP) has been reported in approximately 10 to 20% of patients in whom it was measured. Retention was usually minimal but was elevated during prolonged clomiphene citrate administration or with apparently unrelated liver disease. In some patients, pre-existing BSP retention decreased even though clomiphene citrate therapy was continued. Other liver function tests were usually normal.
Other Laboratory Studies
Clomiphene citrate has not been reported to cause a significant abnormality in hematologic or renal tests, in protein bound iodine, or in serum cholesterol levels.
Birth Defects
Of 1803 births following clomiphene citrate administration, 45 infants with birth defects were reported for a cumulative rate of 2.5%.
Six cases of Down's Syndrome, one neonatal death with multiple malformations and one case each of the following were reported: extropia, club foot, tibial torsion, blocked tear duct and hemangioma. The other congenital abnormalities were not described. The investigators did not report that these were presumed to be due to therapy. The cumulative rate of congenital abnormalities does not exceed that reported in the general population.
Available only on prescription

The challenge of change revisited 505
Frank C. Greiss, Jr., MD
Winston-Salem, North Carolina

Effects of terbutaline sulfate on fetal cardiac function 509
Ruth Petersen, MD, Laurence S. Carter, BS, Nancy C. Chescheir, MD, Vern L. Katz, MD, and Robert C. Cefalo, MD, PhD
Chapel Hill, North Carolina

After long-term exposure to terbutaline, guinea pig fetuses demonstrate myocardial adaptations that predispose them to impaired cardiac function.

Analysis of fetal loss after transcervical chorionic villus sampling—A review of 719 patients 513
Ronald V. Wade, MD, and S. Robert Young, PhD
Columbia, South Carolina

In a study of 714 patients, risk of fetal loss after transcervical chorionic villus sampling is associated with the increasing number of catheter insertions.

Satisfaction realized:

87% patient continuation rate† with Ortho ALL-FLEX* Arcing Spring Diaphragm.

Easy for patient to insert—
the Ortho ALL-FLEX* Diaphragm folds easily.

Easy for patient to correctly position in vagina—
the Ortho ALL-FLEX* Diaphragm can be compressed at any two opposing points around the rim.

Easy to use with **GYNOL II* (2% nonoxynol-9) Contraceptive Jelly**—
greaseless, odorless spermicide.

Easy to clean—one-step molding process eliminates gap between spring and dome so jelly or secretions can't accumulate.

Ortho ALL-FLEX*
DIAPHRAGM

†Percentage of patients continuing the method for 12 consecutive months.

Consult the revised patient brochure for new information on Toxic Shock Syndrome (TSS) and wearing time.

The role of ultrasonography and amniocentesis in the evaluation of pregnancies at risk for neural tube defects 520

William A. Hogge, MD, Siva Thiagarajah, MD, James E. Ferguson II, MD, Patricia T. Schnatterly, MS, and Guy M. Harbert, Jr., MD

Charlottesville, Virginia

A study of 225 pregnancies suggests that targeted ultrasonography alone may be a reasonable evaluation alternative to amniocentesis in patients at risk for neural tube defects.

The effects of vibroacoustic stimulation on baseline heart rate, breathing activity, and body movements of normal term fetuses 524

Lawrence D. Devoe, MD, Nancy A. Searle, BA, David A. Ruedrich, MD, Ramon A. Castillo, MD, and William P. Metheny, PhD

Augusta, Georgia

Vibroacoustic stimulation of normal term fetuses results in brief elevation of fetal heart rate baseline without significant long-term effects on breathing or body movements.

Seminoma in pubertal patient with androgen insensitivity syndrome 530

W. Glenn Hurt, MD, Joann N. Bodurtha, MD, Janice B. McCall, MD, and M. Moinuddin Ali, MD

Richmond, Virginia

Complete androgen insensitivity and metastatic seminoma in a pubertal patient is reported.

Successful pregnancy after a liver transplant 532

Cynthia J. Sims, MD, Kathy B. Porter, MD, and Robert A. Knuppel, MD, MPH

Tampa, Florida

Uncomplicated pregnancy and delivery in a patient 35 months after liver transplantation are described.

Subscriptions may begin at any time.

Corometrics puts the power o convex technolog in your han

The Aloka 620...
Outstanding image quality and more useful clinical information!

Practitioner tested and proven, convex array technology eliminates the problem of a narrow near field of view as seen with conventional sector scanners. A full wide aperture is maintained throughout the entire field of view, preserving resolution even at the sides of the sector scan.

Convex scan shows more clinical information.

A wide range of convex transducers is available, including our unique endovaginal probe designed for ease of use, unsurpassed control, and superior image quality. Advanced software includes an on-screen report page. The Aloka 620 — it all adds up to a new level of power and versatility for your office.

For more information or a demonstration call 1-800-624-7265, ext. 453 or 515.

A clinical-pathologic study of mixed müllerian tumors of the uterus over a 16-year period—The Medical College of Georgia experience 533
Donald G. Gallup, MD, Donna S. Gable, MD, O. Eduardo Talledo, MD, and Luther B. Otken, Jr., MD
Augusta, Georgia

The outcome of 40 patients with mixed müllerian tumors of the uterus is correlated with demographic data, pathology, and treatment.

Evaluation of surgical staples in a cesarean section 540
Gene Burkett, MD, L. P. Jensen, MD, A. Lai, MD, M. J. O'Sullivan, MD, S. Yasin, MD, S. Beydoun, MD, and A. G. W. McLeod, MD
Miami, Florida

Absorbable staples reduced postoperative morbidity in cesarean section, but their use was not time-saving.

Outpatient triplet management: A contemporary review 547
Roger B. Newman, MD, Cheryl Hamer, RN, BS, and M. Clinton Miller, PhD
Charleston, South Carolina

A total of 198 triplet gestations were managed primarily on an outpatient basis and were delivered between 1985 and 1988 with a perinatal survival rate of 95%.

Maternal mortality in North Carolina: A forty-year experience 555
W. Joseph May, MD, and Frank C. Greiss, Jr., MD
Winston-Salem, North Carolina

Although the decrease in pregnancy-related death rates continues in North Carolina, variable trends in causal groups emerge and nonwhite/white relative risk remains high.

Risk factors for intraamniotic infection: A prospective epidemiologic study 562
David E. Soper, MD. C. Glen Mayhall, MD, and Harry P. Dalton, PhD
Richmond, Virginia

Logistic regression analysis identified four variables independently associated with intraamniotic infection.

Short course of antibiotic therapy in treatment of postpartum endomyometritis 568
Walter J. Morales, MD, PhD, Evan M. Collins, MD, Jeffrey L. Angel, MD, and Robert A. Knuppel, MD, MPH
Orlando, Florida

Through a prospective randomized study, short-course antibiotic therapy with combination tobramycin-clinidamycin was found safe and efficacious in the treatment of postpartum endomyometritis.

Subsequent fertility in women who undergo cardiac surgery 573
Wallace C. Nunley, Jr., MD, Lisa A. Kolp, MD, Laura N. Dabinett, MD, James D. Kitchin III, MD, Bruce G. Bateman, MD, and George B. Craddock, Jr., MD
Charlottesville, Virginia

There was no specific fertility problem identified in women who attempted conception after open heart surgery.

Fertility after ectopic pregnancy 576
Dorothy E. Mitchell, MD, Helen F. McSwain, MD, and Herbert B. Peterson, MD
Atlanta, Georgia

Clinical circumstances, including initial surgical procedure and postoperative hysterosalpingogram, are correlated with subsequent fertility.

Effects of clomiphene citrate on episodic luteinizing hormone secretion throughout the menstrual cycle 581
David F. Archer, MD, Glen Hofmann, MD, PhD, Robert Brzyski, MD, PhD, Barbara Ross, RN, BSN, Richard T. Scott, Jr., MD, Christine B. Philput, PhD, Sergio Oehninger, MD, and J. Catesby Ware, PhD
Norfolk, Virginia

Clomiphene citrate increased pituitary LH secretion in the follicular phase of normal women resulting in an increased serum LH level; the increased LH secretion was associated with an increased amplitude of each identified pulse but without a significant change in pituitary LH pulse frequency.

TRANSACTIONS OF THE NINTH ANNUAL MEETING OF THE SOCIETY OF PERINATAL OBSTETRICIANS

Management of women with one abnormal oral glucose tolerance test value reduces adverse outcome in pregnancy 593
Oded Langer, MD, Akolisa Anyaegbunam, MD, Lois Brustman, MD, and Michael Divon, MD
Bronx, New York

Treatment of women with one abnormal value on the oral glucose tolerance test reduced fetal macrosomia and neonatal metabolic complications to an incidence comparable to that in the normal population.

Routine umbilical cord blood gas determinations? 600
James A. Thorp, MD, Jone E. Sampson, MD, Valerie M. Parisi, MD, MPH, and Robert K. Creasy, MD
Houston, Texas

Results of umbilical cord blood gas determinations in newborns of 1924 nulliparous women are presented and used as a basis for considering obtaining cord arterial pH values at all deliveries.

Contents

Comparison of six different ultrasonographic methods for predicting lethal fetal pulmonary hypoplasia 606

Anthony M. Vintzileos, MD, Winston A. Campbell, MD, John F. Rodis, MD, David J. Nochimson, MD, Michael G. Pinette, MD, and Boris M. Petrikovsky, MD

Farmington, Connecticut

Of six different ultrasonographic methods, the chest area minus heart area/chest area ratio was found to have the best diagnostic accuracy in predicting lethal pulmonary hypoplasia.

Prophylactic amnioinfusion during labor complicated by meconium: A preliminary report 613

Yoel Sadovsky, MD, Erol Amon, MD, Mary E. Bade, BSMT, and Roy H. Petrie, MD, ScD

St. Louis, Missouri

Amnioinfusion decreases the frequency of thick meconium, neonatal acidemia, meconium below the vocal cords, and requirement for positive pressure ventilation during labor complicated by meconium.

Lack of evidence of a vasodepressor role for relaxin in spontaneously hypertensive and normotensive pregnant rats 618

Robert A. Ahokas, PhD, Baha M. Sibai, MD, and Garland D. Anderson, MD

Memphis, Tennessee

Bilateral ovariectomy (removal of the source of relaxin) does not prevent attenuation of angiotensin II pressor responsiveness and vasodilation in pregnant hypertensive or normotensive rats.

Perinatal factors influencing atrial natriuretic peptide levels in umbilical arterial plasma at the time of delivery 623

Lony C. Castro, MD, Chander P. Arora, PhD, Kay E. Roll, RN, Deborah A. Sassoon, MD, and Calvin J. Hobel, MD

Los Angeles, California

Atrial natriuretic peptide levels were higher in the umbilical artery than in the vein and were elevated in cases of preeclampsia and fetal distress.

Impact of antenatal dexamethasone administration on respiratory distress syndrome in surfactant-treated infants 628

Elaine E. Farrell, MD, Richard K. Silver, MD, Lois V. Kimberlin, RN, Eileen S. Wolf, RN, and Joanne M. Dusik, RN

Evanston, Illinois

An additive effect between antenatal dexamethasone and exogenous surfactant that reduced the incidence and severity of RDS was observed in this study; neonatal characteristics associated with a reduced incidence of RDS included singleton birth, delivery between 28 and 32 weeks' gestation, and male gender.

Cocaine abuse during pregnancy: Peripartum prevalence and perinatal outcome 633
Mark G. Neerhof, DO, Scott N. MacGregor, DO, Sandy S. Retzky, DO, and Terence P. Sullivan, DO
Chicago, Illinois

In this study peripartum cocaine abuse was common, increased during the 2-year study period, and was associated with increased perinatal morbidity.

Do the current standards for glucose tolerance testing in pregnancy represent a valid conversion of O'Sullivan's original criteria? 638
David A. Sacks, MD, Salim Abu-Fadil, MD, Jeffrey S. Greenspoon, MD, and Nick Fotheringham, PhD
Bellflower and Los Angeles, California

A formula converting whole blood glucose estimates by the Somogyi-Nelson method to plasma concentrations by the glucose oxidase method for use during pregnancy was empirically derived.

How reliable is the fifty-gram, one-hour glucose screening test? 642
David A. Sacks, MD, Salim Abu-Fadil, MD, Jeffrey S. Greenspoon, MD, and Nick Fotheringham, PhD
Bellflower and Los Angeles, California

A substantial proportion of gestational diabetes may go undiagnosed if reliance is placed on a single 1-hour, 50 gm glucose screening test.

Glycemic control in gestational diabetes mellitus—How tight is tight enough: Small for gestational age versus large for gestational age? 646
Oded Langer, MD, Judith Levy, MD, Lois Brustman, MD, Akolisa Anyaegbunam, MD, Ruth Merkatz, RN, and Michael Divon, MD
Bronx, New York

Targeting the level of glycemic control to an optimal range between 87 and 104 mg/dl in the management of women with gestational diabetes mellitus will result in neonatal size comparable to the general newborn population; thus undertreating and overtreating can result in intrauterine growth retardation and macrosomic fetuses.

Maternal hemoglobin F levels may have an adverse effect on neonatal birth weight in pregnancies with sickle cell disease 654
Akolisa Anyaegbunam, MD, Henny H. Billett, MD, Oded Langer, MD, Lois Brustman, MD, Claudia Berger, BA, Linda Wyse, MD, Ronald L. Nagel, MD, and Irwin R. Merkatz, MD
Bronx, New York

Although high maternal hemoglobin levels may be beneficial to the fetus, higher maternal hemoglobin F levels may have an adverse effect of neonatal birth weight.

Pneumonia during pregnancy: Has modern technology improved maternal and fetal outcome? 657
Nancy E. Madinger, MD, Jeffrey S. Greenspoon, MD, and A. Gray Ellrodt, MD
Los Angeles, California

A retrospective study of pneumonia during pregnancy revealed that maternal morbidity and preterm labor were frequent complications and that the rate of preterm delivery has not decreased in comparison with rates of earlier studies.

Contents

Comparison of predelivery versus postdelivery Kleihauer-Betke stains in cases of fetal death 663

John Owen, MD, Charles M. Stedman, MD, and Tommy L. Tucker, MT(ASCP)

Birmingham, Alabama

The delivery process does not simulate a massive fetomaternal hemorrhage in cases of fetal death.

Uterine rupture: Are intrauterine pressure catheters useful in the diagnosis? 666

M. Hellen Rodriguez, MD, Damon I. Masaki, MD, Jeffrey P. Phelan, MD, and Fidelia G. Diaz, MA

Los Angeles, California

In reviewing 76 cases, the intrauterine pressure catheter was not found to be useful in the diagnosis of uterine rupture.

The effect of continuous epidural analgesia on cesarean section for dystocia in nulliparous women 670

James A. Thorp, MD, Valerie M. Parisi, MD, MPH, Peter C. Boylan, MB, and Dennis A. Johnston, PhD

Houston, Texas

Epidural analgesia in labor may increase the incidence of cesarean section.

Can platelet volume predict progressive hypertensive disease in pregnancy? 676

James J. Walker, MB, ChB, Alan D. Cameron, MB, ChB, Steingrimur Bjornsson, MD, Charles R. J. Singer, MB, ChB, and Carol Fraser, FMILS

Glasgow, Scotland

This study shows that the use of mean platelet volume as a screening test for development of pregnancy-induced hypertension is of no value in the low-risk population, but a rise of mean platelet volume of at least 1 fl does appear to predict patients within a high-risk population who will progress to severe preeclampsia.

Measurement of cardiac output in pregnancy by thoracic electrical bioimpedance and thermodilution 680

Damon I. Masaki, MD, Jeffrey S. Greenspoon, MD, and Joseph G. Ouzounian, BS

Los Angeles, California

Thoracic electrical bioimpedance and thermodilution estimates of cardiac output correlated well (+20%) in eight of nine peripartum patients for whom comparison was valid.

In utero cocaine exposure: Observations of fetal behavioral state may predict neonatal outcome 685

Roderick F. Hume, Jr., MD, Maj, MC, USA, Karen J. O'Donnell, PhD, Cathi L. Stanger, RN, Allen P. Killam, MD, and Jeannine L. Gingras, MD

Durham, North Carolina

Ultrasonographic observation of altered fetal behavioral state organization and regulation successfully predicted abnormal neonatal behavior in perinates who were exposed to cocaine in utero.

(Contents continued on page 14A)

Contents continued from page 13A

In utero diagnosis of benign fetal macrocephaly 690
Robert DeRosa, MD, Roger R. Lenke, MD, Thaddeus W. Kurczynski, MD, Wayne H. Persutte, BS, RDMS, and Joanne M. Nemes, RNC, BSN
Toledo, Ohio

A case of benign familial macrocephaly was diagnosed prenatally by serial ultrasonographic evaluations and family history.

Rapid determination of fetal sex by deoxyribonucleic acid amplification of Y chromosome-specific sequences 693
Thomas L. Pinckert, MD, Roger V. Lebo, PhD, and Mitchell S. Golbus, MD
San Francisco, California

The polymerase chain reaction sex test amplifies and identifies male-specific sequences to quickly and correctly determine fetal sex.

"Possibly" de novo translocations: Prenatal risk counseling 698
E. Robert Wassman, MD, Debra L. Cheyovich, DrPH, and Yasunori Nakahara, MD
Pasadena, California

Apparently balanced translocations found incidentally at prenatal diagnosis in a large series show little difference in outcome from normal, but conservative counseling should be done.

Amniotic fluid acetylcholinesterase ratios in prenatal diagnosis of fetal abnormalities 703
JoAnn C. Kelly, PhD, Elizabeth Petrocik, and E. Robert Wassman, MD
Pasadena, California

The ratio of amniotic fluid acetylcholinesterase in pseudocholinesterase is useful in differentiating pregnancies with neural tube defects, ventral wall defects, blood contamination, and other problems.

Effect of diagnostic and therapeutic cordocentesis on maternal serum α-fetoprotein concentration 706
Carl Weiner, MD, Stanley Grant, RN, Jerry Hudson, PhD, Roger Williamson, MD, and Katharine Wenstrom, MD
Iowa City, Iowa

Maternal serum α-fetoprotein rose after cordocentesis to a similar degree for that reported after amniocentesis.

Two hundred intrauterine exchange transfusions in severe blood incompatibilities 709
Marie-Héléne Poissonnier, MD, Yves Brossard, MD, Nicole Demedeiros, MD, Juliana Vassileva, MD, Françoise Parnet, MD, Marc Larsen, MD, Monique Gosset, Jacques Chavinie, MD, and Jacques Huchet, MD
Paris, France

Sixty severely anemic fetuses and 47 with hydrops were treated with a success rate of 91.6% and 61.7%, respectively.

Contents

Normal values for human umbilical venous and amniotic fluid pressures and their alteration by fetal disease 714

Carl P. Weiner, MD, Joni Heilskov, RN, Gay Pelzer, RN, Stanley Grant, RN, Katharine Wenstrom, MD, and Roger A. Williamson, MD

Iowa City, Iowa

Human amniotic fluid and fetal umbilical venous pressure are altered by a variety of spontaneously occurring disorders.

Ovine fetal cardiorespiratory response to nicardipine 718

R. Harold Holbrook, Jr., MD, Ellen M. Voss, BS, and Ronald N. Gibson, BS

Stanford, California

Direct administration of the calcium antagonist nicardipine to the ovine fetus was not associated with the significant cardiorespiratory changes previously reported with maternal administration.

Effect of prolonged hypoxemia on fetal heart rate accelerations and decelerations in sheep 722

Alan D. Bocking, MD, Susan White, BSc, Robert Gagnon, MD, and Howard Hansford

London, Ontario, Canada

Hypoxemia was maintained for 24 hours in fetal sheep by restricting uterine blood flow, which led to an initial increase in the number of fetal heart rate accelerations and decelarations followed by a return to normal patterns by 12 to 16 hours.

Prolonged hyperinsulinemia reduces plasma fatty acid levels in the major lipid groups in fetal sheep 728

Paul L. Ogburn, Jr., MD, Marshall Goldstein, MD, Jane Walker, BS, and Barbara S. Stonestreet, MD

Providence, Rhode Island

Prolonged infusion of insulin into fetal sheep lowered the major plasma fatty acid levels (with the exception of linoleic acid) in triglycerides, phospholipids, and nonesterified fatty acids.

Pharmacokinetics of azidothymidine during late pregnancy in Long-Evans rats 732

B. B. Little, MA, PhD, R. E. Bawdon, PhD, J. T. Christmas, MD, S. Sobhi, BS, and L. C. Gilstrap III, MD

Dallas, Texas

Placental transfer of azidothymidine was studied in pregnant rats and was found to equilibrate rapidly into the fetal compartment but at levels significantly lower than initial maternal levels.

Ultrastructural aspects of preeclampsia. I. Placental bed and uterine boundary vessels 735

Douglas R. Shanklin, MD, and Baha M. Sibai, MD

Memphis, Tennessee

Direct-vision uterine biopsies obtained at cesarean section or from section hysterectomy showed extensive ultrastructural endothelial injury in patients with preeclampsia but not in normotensive patients.

Birth weight prediction from remote ultrasonographic examination 742
Joseph A. Spinnato, MD, Robert D. Allen, and Hiram W. Mendenhall, MD
Mobile, Alabama

Five existing static equations were remodeled to permit birth weight estimates from remote ultrasonographic parameters.

Dating the early pregnancy by sequential appearance of embryonic structures 747
Wendy B. Warren, MD, Ilan Timor-Tritsch, MD, David B. Peisner, MD, Sashi Raju, and Mortimer G. Rosen, MD
New York, New York

The transvaginal sonographic appearance of embryonic structures was used as a method of dating the early first-trimester pregnancy.

Macrosomia in the postdate pregnancy: Is routine ultrasonographic screening indicated? 753
Judith L. Chervenak, MD, Michael Y. Divon, MD, Jordan Hirsch, MD, Barbara A. Girz, DO, and Oded Langer, MD
Bronx, New York, and Newark, New Jersey

Ultrasonographic screening for macrosomia may be a valuable adjunct to current fetal surveillance protocols used in the postdate pregnancy.

Discordant twins—A prospective study of the diagnostic value of real-time ultrasonography combined with umbilical artery velocimetry 757
Michael Y. Divon, MD, Barbara A. Girz, DO, Avi Sklar, MD, Denise A. Guidetti, MD, and Oded Langer, MD
Bronx, New York

The presence of either a 15% difference in ultrasonographic estimates of fetal weight or a 15% difference in systolic/diastolic ratios correctly identified 78% of discordant pairs.

Doppler umbilical artery waveform indices—Normal values from fourteen to forty-two weeks 761
Susan K. Hendricks, MD, Tanya K. Sorensen, MD, Keith Y. Wang, MD, PhD, Jeanette M. Bushnell, MSN, Elaine M. Seguin, RNC, and Rosalee W. Zingheim, BSN
Seattle, Washington

Fetal velocimetry was performed in 590 low-risk cases and normal values are reported for 14 to 42 weeks' gestation.

Screening with Doppler velocimetry in labor 765
Leonard Feinkind, MD, Ovadia Abulafia, MD, Isaac Delke, MD, Joseph Feldman, MD, and Howard Minkoff, MD
Brooklyn, New York

Doppler velocimetry in 273 laboring patients was correlated with the nonstress test result on presentation and was predictive of fetal outcome.

Contents

The effect of magnesium sulfate tocolysis on the fetal biophysical profile 771
Alan M. Peaceman, MD, Bruce A. Meyer, MD, James A. Thorp, MD, Valerie M. Parisi, MD, MPH, and Robert K. Creasy, MD
Houston, Texas

Magnesium sulfate tocolysis causes nonreactive nonstress testing and cessation of breathing movements in a significant number of fetuses, without affecting tone, movements, or amniotic fluid volume.

Controlled trial of hydration and bed rest versus bed rest alone in the evaluation of preterm uterine contractions 775
Richard A. Pircon, MD, Howard T. Strassner, MD, Donna S. Kirz, MD, and Craig V. Towers, MD
Orange and Long Beach, California, and Chicago, Illinois

The use of hydration as a therapy to differentiate those with true preterm labor from those with false preterm labor could not be supported.

Fetal heart rate patterns in the small-for-gestational-age human fetus 779
Robert Gagnon, MD, Cora Hunse, RN, and Alan D. Bocking, MD
London, Ontario, Canada

Currently used criteria for nonstress testing may not be clinically applicable in growth-retarded human fetuses.

Impact of residual amniotic fluid volume in patients receiving parenteral tocolysis after premature rupture of the membranes 784
Richard K. Silver, MD, Scott N. MacGregor, DO, and Edward D. Hobart
Evanston, Illinois

Diminished residual amniotic fluid volume in patients with premature membrane rupture who are receiving tocolytic therapy is associated with a significant decrease in latency.

Cardiovascular and metabolic effects associated with nifedipine and ritodrine tocolysis 788
James E. Ferguson II, MD, Donald C. Dyson, MD, R. Harold Holbrook, Jr., MD, Thomas Schutz, BA, and David K. Stevenson, MD
Santa Clara and Stanford, California

Cardiovascular and metabolic effects of nifedipine or ritodrine tocolysis were compared; minimal effects were noted when nifedipine was used.

Prolactin levels in umbilical cord blood of human infants: Relation to gestational age, maternal complications, and neonatal lung function 795
C. Richard Parker, Jr., PhD, Paul C. MacDonald, MD, David S. Guzick, MD, John C. Porter, PhD, Charles R. Rosenfeld, MD, and John C. Hauth, MD
Birmingham, Alabama, and Dallas, Texas

In a study involving 543 infants, 361 of whom were preterm, subnormal serum prolactin levels were found in infants who developed respiratory distress syndrome.

Contents continued from page 17A

Amniotic fluid leukotaxis assay as an early indicator of chorioamnionitis 802
Glenn A. Pankuch, BS, Peter H. Cherouny, MD, John J. Botti, and Peter C. Appelbaum, MD, PhD
Hershey, Pennsylvania

Detection of leukoattractants in amniotic fluid correlates more accurately with histologic chorioamnionitis than culture, gas-liquid chromatography, and Gram stain.

Evidence relating bacterial vaginosis to intraamniotic infection 808
Helayne M. Silver, MD, Rhoda S. Sperling, MD, Patricia J. St. Clair, BA, and Ronald S. Gibbs, MD
San Antonio, Texas

In a two-part study, we provide evidence that links bacterial vaginosis with clinically evident intraamniotic infection.

The incidence of positive amniotic fluid cultures in patients in preterm labor with intact membranes 813
M. Amanda Skoll, MD, Michael L. Moretti, MD, and Baha M. Sibai, MD
Memphis, Tennessee

Amniotic fluid cultures were performed on 127 women in preterm labor with intact membranes; positive cultures were found in 5.5%.

Infection and labor. V. Prevalence, microbiology, and clinical significance of intraamniotic infection in women with preterm labor and intact membranes 817
Roberto Romero, MD, Marina Sirtori, MD, Enrique Oyarzun, MD, Cecilia Avila, MD, Moshe Mazor, MD, Robert Callahan, BS, Virginia Sabo, MSN, Apostolos Athanassiadis, MD, and John C. Hobbins, MD
New Haven, Connecticut

Intraamniotic infection is present in one of every five women with preterm labor and intact membranes who is delivered of a preterm newborn.

Diagnosis of birth asphyxia based on fetal pH, Apgar score, and newborn cerebral dysfunction 825
Larry C. Gilstrap III, MD, Kenneth J. Leveno, MD, Jody Burris, RN, M. Lynne Williams, RN, and Bertis B. Little, PhD
Dallas, Texas

It is inappropriate to diagnose birth affixia unless the infant is severely depressed (1- and 5-minute Apgar scores of ≤ 3) and has severe metabolic acidosis at birth (umbilical artery blood pH <7.000).

First-trimester midgut herniation: A high-frequency transvaginal sonographic study 831
Ilan E. Trimor-Tritsch, MD, Wendy B. Warren, MD, David B. Peisner, MD, and Exenia Pirrone, LPN
New York, New York

The physiologic midgut herniation can reliably be detected between 8 and 12 menstrual weeks by high-frequency transvaginal sonography.

Calcium every day
Aerobics every week
Bone loss every year

She needs PREMARIN to help prevent further bone loss

Calcium[1] and exercise are not enough to prevent post-menopausal osteoporosis, since estrogen deficiency is the primary cause.[2] PREMARIN is the only brand of estrogen indicated to prevent further bone loss and in a recently published study has been shown to reduce the risk of hip fractures by as much as 66%.[3]

Early PREMARIN therapy offers the best protection

The most significant rate of bone loss occurs in early menopause. PREMARIN can help maintain bone mass, preventing the progression of osteoporosis and its consequences.

Protection continues as long as estrogen therapy continues

Clinical studies show that within three years of menopause when therapy is withdrawn, bone loss begins again.[4]

PREMARIN®

(conjugated estrogens tablets)

Proven benefits for menopause and beyond

See important information on adjacent page.

For moderate-to-severe vasomotor symptoms and for osteoporosis

BRIEF SUMMARY *(FOR FULL PRESCRIBING INFORMATION AND PATIENT INFORMATION, SEE PACKAGE CIRCULARS.)*

PREMARIN® Brand of conjugated estrogens tablets, USP
PREMARIN® Brand of conjugated estrogens Vaginal Cream, in a nonliquefying base

1. ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA.
Three independent, case-controlled studies have reported an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for more than one year. This risk was independent of the other known risk factors for endometrial cancer. These studies are further supported by the finding that incidence rates of endometrial cancer have increased sharply since 1969 in eight different areas of the United States with population-based cancer reporting systems, an increase which may be related to the rapidly expanding use of estrogens during the last decade. The three case-controlled studies reported that the risk of endometrial cancer in estrogen users was about 4.5 to 13.9 times greater than in nonusers. The risk appears to depend on both duration of treatment and on estrogen dose. In view of these findings, when estrogens are used for the treatment of menopausal symptoms, the lowest dose that will control symptoms should be utilized and medication should be discontinued as soon as possible. When prolonged treatment is medically indicated, the patient should be reassessed on at least a semi-annual basis to determine the need for continued therapy. Although the evidence must be considered preliminary, one study suggests that cyclic administration of low doses of estrogen may carry less risk than continuous administration; it therefore appears prudent to utilize such a regimen. Close clinical surveillance of all women taking estrogens is important. In all cases of undiagnosed persistent or recurring abnormal vaginal bleeding, adequate diagnostic measures should be undertaken to rule out malignancy. There is no evidence at present that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equi-estrogenic doses.
2. ESTROGENS SHOULD NOT BE USED DURING PREGNANCY.
The use of female sex hormones, both estrogens and progestogens, during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing, in later life, a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated as not greater than 4 per 1,000 exposures. Furthermore, a high percentage of such exposed women (from 30% to 90%) have been found to have vaginal adenosis, epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are precursors of malignancy. Although similar data are not available with the use of other estrogens, it cannot be presumed they would not induce similar changes. Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies, including congenital heart defects and limb-reduction defects. One case-controlled study estimated a 4.7-fold increased risk of limb-reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than 1 per 1,000. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. If PREMARIN is used during pregnancy, or if the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus, and the advisability of pregnancy continuation.

DESCRIPTION: PREMARIN (conjugated estrogens, USP) contains a mixture of estrogens, obtained exclusively from natural sources, blended to represent the average composition of material derived from pregnant mares' urine. It contains estrone, equilin, and 17α-dihydroequilin, together with smaller amounts of 17α-estradiol, equilenin, and 17α-dihydroequilenin as salts of their sulfate esters. Tablets are available in 0.3 mg, 0.625 mg, 0.9 mg, 1.25 mg, and 2.5 mg strengths of conjugated estrogens. Cream is available as 0.625 mg conjugated estrogens per gram.

INDICATIONS AND USAGE: PREMARIN (conjugated estrogens tablets, USP): Moderate-to-severe *vasomotor* symptoms associated with the menopause. (There is no evidence that estrogens are effective for nervous symptoms or depression without associated vasomotor symptoms and they should not be used to treat such conditions.) Osteoporosis (abnormally low bone mass). Atrophic vaginitis. Kraurosis vulvae. Female castration.

PREMARIN (conjugated estrogens) Vaginal Cream is indicated in the treatment of atrophic vaginitis and kraurosis vulvae.

PREMARIN HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETUS (SEE BOXED WARNING).

CONTRAINDICATIONS: Estrogens should not be used in women (or men) with any of the following conditions: 1. Known or suspected cancer of the breast except in appropriately selected patients being treated for metastatic disease. 2. Known or suspected estrogen-dependent neoplasia. 3. Known or suspected pregnancy (see Boxed Warning). 4. Undiagnosed abnormal genital bleeding. 5. Active thrombophlebitis or thromboembolic disorders. 6. A past history of thrombophlebitis, thrombosis, or thromboembolic disorders associated with previous estrogen use (except when used in treatment of breast or prostatic malignancy).

WARNINGS: Estrogens have been reported to increase the risk of endometrial carcinoma (see Boxed Warning). However, a recent large, case-controlled study indicated no increase in risk of breast cancer in postmenopausal women. A recent study has reported a 2- to 3-fold increase in the risk of surgically confirmed gallbladder disease in women receiving postmenopausal estrogens.

Adverse effects of oral contraceptives may be expected at the larger doses of estrogen used to treat prostatic or breast cancer or postpartum breast engorgement; it has been shown that there is an increased risk of thrombosis in men receiving estrogens for prostatic cancer and women for postpartum breast engorgement. Users of oral contraceptives have an increased risk of diseases, such as thrombophlebitis, pulmonary embolism, stroke, and myocardial infarction. Cases of retinal thrombosis, mesenteric thrombosis, and optic neuritis have been reported in oral contraceptive users. An increased risk of postsurgery thromboembolic complications has also been reported in users of oral contraceptives. If feasible, estrogen should be discontinued at least 4 weeks before surgery of the type associated with an increased risk of thromboembolism, or during periods of prolonged immobilization. Estrogens should not be used in persons with active thrombophlebitis, thromboembolic disorders, or in persons with a history of such disorders in association with estrogen use. They should be used with caution in patients with cerebral vascular or coronary artery disease. Large doses (5 mg conjugated estrogens per day), comparable to those used to treat cancer of the prostate and breast, have been shown to increase the risk of nonfatal myocardial infarction, pulmonary embolism, and thrombophlebitis. When doses of this size are used, any of the thromboembolic and thrombotic adverse effects should be considered a clear risk.

Benign hepatic adenomas should be considered in estrogen users having abdominal pain and tenderness, abdominal mass, or hypovolemic shock. Hepatocellular carcinoma has been reported in women taking estrogen-containing oral contraceptives. Increased blood pressure may occur with use of estrogens in the menopause and blood pressure should be monitored with estrogen use. A worsening of glucose tolerance has been observed in patients on estrogen-containing oral contraceptives. For this reason, diabetic patients should be carefully observed. Estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases.

PRECAUTIONS: Physical examination and a complete medical and family history should be taken prior to the initiation of any estrogen therapy with special reference to blood pressure, breasts, abdomen, and pelvic organs, and should include a Papanicolaou smear. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination being performed. Conditions influenced by fluid retention, such as asthma, epilepsy, migraine, and cardiac or renal dysfunction, require careful observation. Certain patients may develop manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding, mastodynia, etc. Prolonged administration of unopposed estrogen therapy has been reported to increase the risk of endometrial hyperplasia in some patients. Oral contraceptives appear to be associated with an increased incidence of mental depression. Patients with a history of depression should be carefully observed. Pre-existing uterine leiomyomata may increase in size during estrogen use. The pathologist should be advised of estrogen therapy when relevant specimens are submitted. If jaundice develops in any patient receiving estrogen, the medication should be discontinued while the cause is investigated. Estrogens should be used with care in patients with impaired liver function, renal insufficiency, metabolic bone diseases associated with hypercalcemia, or in young patients in whom bone growth is not yet complete. If concomitant progestin therapy is used, potential risks may include adverse effects on carbohydrate and lipid metabolism.

Concomitant Progestin Use: The lowest effective dose appropriate for the specific indication should be utilized. Studies of the addition of a progestin for 7 or more days of a cycle of estrogen administration have reported a lowered incidence of endometrial hyperplasia. Morphological and biochemical studies of the endometrium suggest that 10 to 13 days of progestin are needed to provide maximal maturation of the endometrium and to eliminate any hyperplastic changes. Whether this will provide protection from endometrial carcinoma has not been clearly established. There are possible additional risks which may be associated with the inclusion of progestin in estrogen replacement regimens. The choice of progestin and dosage may be important in minimizing possible adverse effects.

The following changes may be expected with larger doses of estrogen:

a. Increased sulfobromophthalein retention.

b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.

c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by PBI, T_4 by column, or T_4 by radioimmunoassay. Free T_3 resin uptake is decreased, reflecting the elevated TBG; free T_4 concentration is unaltered.

d. Impaired glucose tolerance.

e. Decreased pregnanediol excretion.

f. Reduced response to metyrapone test.

g. Reduced serum folate concentration.

h. Increased serum triglyceride and phospholipid concentration.

As a general principle, the administration of any drug to nursing mothers should be done only when clearly necessary since many drugs are excreted in human milk.

Long-term, continuous administration of natural and synthetic estrogens in certain animal species increases the frequency of carcinomas of the breast, cervix, vagina, and liver. However, in a recent, large case-controlled study of postmenopausal women there was no increase in risk of breast cancer with use of conjugated estrogens.

ADVERSE REACTIONS: The following have been reported with estrogenic therapy, including oral contraceptives: breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea; premenstrual-like syndrome; amenorrhea during and after treatment; increase in size of uterine fibromyomata; vaginal candidiasis; change in cervical erosion and in degree of cervical secretion; cystitis-like syndrome; tenderness, enlargement, secretion (of breasts); nausea, vomiting, abdominal cramps, bloating; cholestatic jaundice; chloasma or melasma which may persist when drug is discontinued; erythema multiforme; erythema nodosum; hemorrhagic eruption; loss of scalp hair; hirsutism; steepening of corneal curvature; intolerance to contact lenses; headache, migraine, dizziness, mental depression, chorea; increase or decrease in weight; reduced carbohydrate tolerance; aggravation of porphyria; edema; changes in libido.

ACUTE OVERDOSAGE: May cause nausea, and withdrawal bleeding may occur in females.

DOSAGE AND ADMINISTRATION:

PREMARIN® Brand of conjugated estrogens tablets, USP

1. *Given cyclically for short-term use only.* For treatment of moderate-to-severe *vasomotor* symptoms, atrophic vaginitis, or kraurosis vulvae associated with the menopause (0.3 mg to 1.25 mg or more daily). The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible. Administration should be cyclic (eg, three weeks on and one week off). Attempts to discontinue or taper medication should be made at three- to six-month intervals.

2. *Given cyclically:* Osteoporosis. Female castration. Osteoporosis —0.625 mg daily. Administration should be cyclic (eg, three weeks on and one week off). Female castration—1.25 mg daily, cyclically. Adjust upward or downward according to response of the patient. For maintenance, adjust dosage to lowest level that will provide effective control.

Patients with an intact uterus should be monitored for signs of endometrial cancer and appropriate measures taken to rule out malignancy in the event of persistent or recurring abnormal vaginal bleeding.

PREMARIN® Brand of conjugated estrogens Vaginal Cream

Given cyclically for short-term use only. For treatment of atrophic vaginitis or kraurosis vulvae.

The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible.

Administration should be cyclic (eg, three weeks on and one week off).

Attempts to discontinue or taper medication should be made at three- to six-month intervals.

Usual dosage range: 2 g to 4 g daily, intravaginally, depending on the severity of the condition.

Treated patients with an intact uterus should be monitored closely for signs of endometrial cancer and appropriate diagnostic measures should be taken to rule out malignancy in the event of persistent or recurring abnormal vaginal bleeding.

INFORMATION FOR AUTHORS

Editorial policies

The requirements for manuscripts submitted to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors and published in *Annals of Internal Medicine* 1988;108:258-65. Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL, and in more detail in the *Guide to Writing for the American Journal of Obstetrics and Gynecology*. The latter may be obtained from The C.V. Mosby Company or the Editors on request.

Manuscript submission. Manuscripts should be submitted to one of the three Editors as follows:

1. **Dr. Brewer**—all manuscripts originating from the southeastern quadrant of the United States or Canada and those presented before one of the official sponsoring societies, except the Society for Gynecologic Investigation and The Society of Perinatal Obstetricians.

2. **Dr. Zuspan**—manuscripts from the northeastern quadrant of the United States and from Japan, Israel, Italy, and England, manuscripts written for Clinical Opinion and Current Development, and Letters to the Editors. Dr. Zuspan is responsible for manuscripts from The Society of Perinatal Obstetricians. Manuscripts from The Society of Perinatal Obstetricians should be submitted to Dr. John A. Read, 9102 Lake Steilacoom Point Road, S.W., Tacoma, WA 98498.

3. **Dr. Quilligan**—manuscripts from the north central states (including Ohio), states west of the Mississippi River, Hawaii, Alaska, and abroad (except Japan, Israel, Italy, and England). Dr. Quilligan is responsible for manuscripts from the Society for Gynecologic Investigation. Manuscripts from the Society for Gynecologic Investigation should be submitted to Dr. Roger A. Lobo, Women's Hospital, 1240 North Mission Road, Room 1M2, Los Angeles, CA 90033.

Author's designation of reviewers. When authors submit their manuscripts, they may provide the names and addresses of three reviewers for consideration by the Editors.

Copyright statement. Effective July 1, 1988, all manuscripts must be accompanied by the following written statement, signed by *all* authors: "The undersigned author(s) transfers all copyright ownership of the manuscript [title of article] to The C.V. Mosby Company in the event the work is published. The undersigned author(s) warrants that the article is original; is not under consideration by another publication; and its essential substance, tables, or figures have not been previously published. This restriction does not apply to abstracts or press reports published in connection with scientific meetings. The author(s) confirms the final manuscript has been read and each author's contribution has been approved by the appropriate author. The author(s) responsible for the manuscript must be identified."

Previous publication. If a report by the same author(s) has been previously published in any medium that deals in any respect whatever with the same patients, same animals, same laboratory experiments, or same data, in part or in full, as those reported in the manuscript being submitted, two reprints of the article or two copies of the manuscript, be it a full-length report or an abstract, must be submitted with the manuscript. The author(s) should inform the Editor of the circumstances of the two reports. This requirement also applies to the submission of a manuscript in which a few different patients, animals, laboratory experiments, or data were added to those reported in a previous publication or in a submitted or accepted manuscript. Articles previously published in another language will not be considered.

Human and animal experimentation. It is assumed by the Editors that manuscripts emanating from a particular

institution are submitted with the approval of the requisite authority. Human experimentation that requires local institutional approval must have this approval *before the experiment is started* and approval must be so indicated in the Methods section of the submitted manuscript. Reports of experiments on animals must *state in the Methods section of the manuscript* that the guidelines for the care and use of the animals *approved by the local institution* were followed.

Authorship. For manuscripts with two or more authors, each author must qualify by having participated actively and sufficiently in the study that is being performed and reported. The inclusion of each author in the authorship list of a report is based only (1) on substantial contributions to (a) concept and design, or analysis and interpretation of data and (b) drafting the manuscript or revising it critically for important intellectual content; and (2) on final approval by each author of the version of the manuscript. Conditions 1 (a and b) and 2 must both be met. Others contributing to the work should be recognized separately in an Acknowledgment. In the covering letter that accompanies the submitted manuscript, it must be confirmed that all authors fulfilled both conditions.

Conflict of interest. Authors are expected to inform the Editor, in a letter accompanying the submitted manuscript, of any commercial association that might pose a conflict of interest, such as ownership, stock holdings, equity interests and consultant activities, or patent-licensing situations. Such information is confidential, is not given to the consultants, and does not play a part in the decision of the quality or timeliness of the manuscript. If the manuscript is accepted, the author and the Editor will determine how best to release the information. The usual and customary listing of sources of support and institutional affiliations on the title page is proper and does not imply a conflict of interest; only where there is a possible conflict of interest is the author(s) expected to inform the Editor.

Disclaimer. Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or publisher, and the Editor(s) and publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality photocopies of the manuscript and three sets of glossy prints of illustrations are required.

Manuscripts must be typed double-spaced on one side only of 22 × 28 cm (8½ × 11 inch) white bond paper with 1-inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, condensation, abstract, body of text, acknowledgments, references, legends, and tables.

Title page. The title page (page 1) should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of each author and each author's highest academic degree (both MD and PhD are acceptable); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; source(s) of financial support; presented line, if applicable; disclaimers, if any; name, address, and business and home telephone numbers of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name, address, and business and home telephone numbers of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).

Condensation. On page 2 of the manuscript provide a brief, concise condensation, typed double-spaced, that will appear with the title in publication of the Contents pages of the JOURNAL. It should be a single sentence, limited to a maximum of 25 words, delineating the essential point(s) made in the manuscript.

Abstract page and key words/phrases. On manuscript page 3 type the abstract, double-spaced, with the required margins and headed by the title of the article and name(s) of author(s). Abstracts for regular articles, Current Investigation, Clinical Opinion, and Current Development may not exceed 150 words. Abstracts for case reports and brief communications may not exceed 50 words. Below the abstract list 3 to 5 *key words* or short phrases for indexing purposes.

Text. Do not hesitate to write your manuscript in the first-person, active voice if it is more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations, since the emphasis is on the "action" rather than on the person performing the action.

Only standard abbreviations are to be used. Consult the *Council of Biology Editors Style Manual* or the AMA's *Manual for Authors and Editors*. Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify Material and Methods, Results, and Comment. Authors may wish to summarize their findings in a short paragraph at the end of the Comment section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the *Material and Methods* section describe briefly (but in sufficient detail to permit other workers to evaluate and reproduce the results) the plan, patients and/or experimental animals and controls, methods and procedures utilized, and statistical method(s) employed.

In the *Results* section present the detailed findings. Include mentions of all tables and/or figures. Avoid duplication of text and supporting material. Emphasize only your important observations; do not compare your

Estimating length of manuscripts

The length of text material (introduction through Comment section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A 4200-word text can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7-page article in the JOURNAL. The 2000 words of text alone make approximately 8 pages of manuscript typed double-spaced with the required 1-inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a JOURNAL page is equivalent to approximately 500 words in manuscript. Thus, if a greater number of illustrations and tables are used, the length of the text should be adjusted accordingly.

observations with those of others. Such comparisons and comments are reserved for the Comment section.

In the *Comment* section state the importance and significance of your findings but do not repeat the details given in the Results section. Limit your opinions to those strictly indicated by the facts in your report. Compare your findings with those of others. No new data should be presented in this section.

Acknowledgments. Acknowledge only persons who have made substantive contributions to the study.

References. A reasonable number are allowed, except in case reports and brief communications (limited to 2) and in manuscripts for the Current Development section (for which there is no limit). Number references consecutively in the order in which they are mentioned in the text. Use the format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" (Vancouver style) (Ann Intern Med 1988;108:258-65). Journal titles should conform to abbreviations used in *Cumulated Index Medicus*.

Examples (if six or fewer authors, list all; if seven or more authors, list three then et al.):

JOURNAL: Flamm BL, Fischermann E, Quilligan EJ, et al. Vaginal delivery following cesarean section—use of oxytocin augmentation and epidural anesthesia. AM J OBSTET GYNECOL 1984;148:759-63.

BOOKS: James VHT, Folkerd EJ, Bonney RC, Beranek PA, Reed MJ. Factors influencing estrogen production and metabolism in postmenopausal women with endocrine cancer. In: van Herendael HB, Riphagen FE, Goessens L, van der Pas H, eds. The climacteric, an update. Lancaster, England: MTP Press, 1983:29.

Personal communications and unpublished data, if essential, may be used but not as numbered references. If they are used, they are to be referred to, within parentheses, at the appropriate location in the text. If used, the author(s) must obtain written and signed permission for their use from the individual being quoted. This signed permission must accompany the manuscript when it is submitted to the Editor. Abstracts are not acceptable as numbered references.

Illustrations and tables. Illustrations and tables should supplement, not duplicate, the text; presentation of data in either one or the other will suffice.

A reasonable number of halftone and line illustrations will be reproduced without charge, but special arrangements must be made with the Editors for *color illustrations* at a cost of $525 per page (one side).

For *color photographs* submit original transparencies and two sets of unmounted prints on glossy (smooth-surface) paper. Polaroid prints are not acceptable. Color transparencies must have a color balance (consistency in lighting and film speed) that is acceptable to the author and Editors before acceptance for publication. Please note that 35 mm transparencies are enlarged to twice their original size. If it is important to deviate from this standard, please so indicate when the material is submitted. The *top, first author's last name,* and *figure number* must be indicated on the front of each transparency and the back of each print. Consistency in size of illustrations within the article is strongly preferred.

For *black-and-white illustrations* submit three sets of 3 × 4 inch (minimum) to 5 × 7 inch (maximum) unmounted, glossy photographic prints. All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. All lettering must be in proportion to the drawing, graph, or photograph. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy photographic prints with good black-and-white contrast. Consistency in size within the article is strongly preferred. Any special instructions regarding sizing should be clearly noted.

Do not use paper clips or mar the surface of prints in any way.

Figures must be cited consecutively in the text in Arabic numerals and identified thusly on the back of the print (gummed label with): author(s) name(s), title of article, number, and top marked clearly.

Figures will be returned only on request by the author.

Tables should be typed on separate sheets of paper, one table to a page, and included at the end of the text. They should be numbered in Roman numerals. Each table must be cited in sequence at an appropriate point in the text. Captions should be brief yet indicate clearly the purpose or content of each table, and each column should be precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. *If a table or any part thereof has been taken from copyrighted material, a legend to the table must give full credit to the original source.* Special arrangements must be made with the Editors for elaborate tables because of space limitations.

Legends to illustrations. Legends for all figures must be typed double-spaced on paper separate from the text of the manuscript, and these pages must be numbered in sequence after the references. Titles should be included in

the legend, *not* on the print. Original magnifications should be provided. *If an illustration has been taken from copyrighted material, the legend must give full credit to the original source.*

Computer-generated illustrations. *Black-and-white illustrations* submitted must be legible and clearly printed in jet-black ink on heavy coated paper with either a glossy or dull finish. Any patterns or shadings must be dark enough for reproduction and must be distinguishable from each other. Lines, symbols, and letters should be both smooth and complete. The legend for the illustration should not appear on the print. On the back of each print the name of the first author and the figure number should be given and the top indicated. Original individual laser or plotter prints are to be submitted *unmounted* with the manuscript. Laser prints should be full size at 300 dots per inch (DPI) or greater full-page resolution; multiple illustrations on a page cannot be accepted. Dot matrix prints and photographic halftones are not acceptable. *Color illustrations* are acceptable, but special arrangements must be made with the Editors. The colors used must be dark enough and of sufficient contrast for reproduction. With the exception of fluorescent colors, all colors can be reproduced in four-color illustrations. The preparation and submitting of color prints should follow the preceding guidelines for black-and-white computer-generated illustrations.

Permissions. Direct quotations, tables, or illustrations that have appeared in copyrighted material must be accompanied by *written permission* for their use from the copyright owner and original author along with complete information as to source. Photographs of identifiable persons must be accompanied by signed releases or else all recognizable features masked.

Requirements for special sections

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include abstract of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title. If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

Current Investigation. Same requirements as for regular article.

Clinical Opinion. Limit of 3000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Current Development. Limit of 6000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Correspondence. Two types of correspondence will be considered for publication. (1) A Letter to the Editors commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. If the original author does not respond, a notation indicating "Response declined" will be published. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a Letter to the Editors will be considered for publication. All letters should be typed double-spaced. The original and a good photocopy must be submitted. Letters should be sent to Dr. Zuspan.

Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of $60 U.S., and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to Kay G. Goehler, Senior Manuscript Editor, Journal Editing, The C.V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Gerbie. No books will be returned.

Reprints

Reprints of articles must be obtained from the author. The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the publisher with the author's consent.

Business communications

Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, The C.V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, or call Journal Advertising Production Manager (314) 872-8370.

Checklist

—Letter of submission
—Copyright transfer letter
—Copies of other manuscripts containing duplicated data (see paragraph "Previous Publication")
—Original and two photocopies of manuscript
—Title page
—Title of article
—Full name(s), highest academic degree(s), and affiliations of author(s)
—Line citing financial support
—Author to whom correspondence is to be sent, including address and business and home telephone numbers
—Reprint requests line or line stating reprints not available
—Short title
—Condensation (double-spaced)
—Abstract (double-spaced), 3 to 5 key words/phrases
—Article proper (double-spaced)
—References (double-spaced), on a separate sheet
—Legends (double-spaced), on a separate sheet
—Tables (double-spaced), on a separate sheet
—Illustrations, properly labeled (three sets of glossy prints)
—Permission to reproduce published material
—Informed consent for patient photographs

MATERNAL-FETAL MEDICINE OPPORTUNITIES

Representative sample of our ongoing opportunities nationwide

CALIFORNIA:
Private Practice Partnership

794 M/F - Outstanding partnership opportunity in central California to assist the current perinatologist in developing a regional perinatal center and network based at a modern 450-bed full service community hospital with over 5,000 deliveries annually. Candidates with a keen interest in ultrasound, genetic procedures, UBS, and teaching should explore this opportunity. There is a documented service area of over two million residents, and you are only one hour from Yosemite and a pleasant drive to the Pacific Shores.

COLORADO:
Hospital-Based/Private Practice

772 M/F - A 328-bed premier Denver area hospital is seeking a perinatologist to complement their 40 active OB/GYN's and full range of obstetrical services. Documented service area is over 800,000 with annual deliveries of 4,200. Level III NICU expanding to 20 beds. Coverage provided by other perinatologists with potential for formal associations. Amenities include the sophistication of a cosmopolitan city, yet minutes away from fantastic skiing, mountain climbing and unlimited water sports.

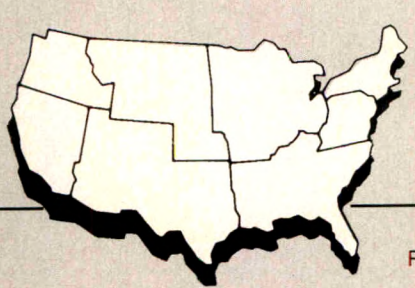
IDAHO:
Hospital-Based/Private Practice

631 M/F - Opportunity to become the second perinatologist in southeastern Idaho, and to affiliate with a 300-bed regional medical center (Level III NICU) which provides a statewide perinatal outreach program. Service area entails 400,000 with over 3,200 annual deliveries. If you enjoy snow skiing, hiking, white water rafting, and a quality of lifestyle like no other, please inquire.

MISSOURI:
Associate/Private Practice

898 M/F - A well-established perinatologist in southwestern Missouri is seeking an associate to join a thriving practice, affiliated with a state-of-the-art 505-bed regional referral center. Service area encompasses over 700,000. Facility has a 52-bed NICU staffed by four neonatologists and a neonatal transport is in place (over 700 admissions per year). Excellent compensation package with long-term growth potential.

OHIO:
Faculty Position/Hospital-Based



831 M/F - A 814-bed regional tertiary care center, in conjunction with the Medical College of Ohio, is seeking their second perinatologist. This is a salaried faculty appointment with the option of flexible private practice capability. The position provides an excellent opportunity to satisfy your professional academic desires within a modern Level III women and children's center, located in a stable northwestern Ohio lakeshore community.

MASSACHUSETTS:
Full-Time Faculty Position

973 OB/GYN/M/F - A 900-bed tertiary care regional referral center in Western Massachusetts is seeking their third perinatologist. This prestigious institution in the designated western campus of Tufts University School of Medicine. The facility has an encatchment area of over 1,000,000 people and it has the second largest maternity unit in the state with over 6,000 deliveries a year. There were 220 transfer deliveries last year and this service continues to grow rapidly. The OB/GYN department owns its own ultrasound equipment (ATL Mark 9) which is housed in the department, plus two full-time technicians and a computerized data base system. The 600 member medical staff is comprised of a full array of subspecialties plus nurse midwives and 20 OB/GYN residents. A new woman & children's center will be completed in early 1991. Competitive compensation with full benefit package is being offered.

Voluntary Hospitals of America

- Over 800 hospitals in 45 states
- Excellent financial and comprehensive benefit packages
- No cost or obligation for our services

"When breakthrough bleeding happened to me I was scared, and that's why I called my doctor."

She deserves a

better start

TRI·LEVLEN®

Levonorgestrel and ethinyl estradiol tablets—Triphasic regimen

54%* less breakthrough bleeding* than Ortho-Novum® 7/7/7

Demonstrated in the largest parallel comparative trial of triphasic OCs to date†[1]

*Serious as well as minor side effects have been reported with the use of all oral contraceptives. The physician should remain alert to the earliest symptoms of serious disease and discontinue oral contraceptive therapy when appropriate. Please see full prescribing information, a brief summary of which follows.

†100 women randomly assigned to Tri-Levlen® tablets or Ortho-Novum® 7/7/7; 50 women placed on nonhormonal contraception as a control. Evaluations were made at baseline and once a month for 6 months.

One cycle of Tri-Levlen® tablets therapy provides: ethinyl estradiol–30 mcg/day for 6 days, 40 mcg/day for 5 days and 30 mcg/day for 10 days; levonorgestrel–50 mcg/day for 6 days, 75 mcg/day for 5 days and 125 mcg/day for 10 days. One cycle of Ortho-Novum® 7/7/7 therapy provides: ethinyl estradiol–35 mcg/day for 21 days; norethindrone–500 mcg/day for 7 days, 750 mcg/day for 7 days and 1000 mcg/day for 7 days.

Ortho-Novum® is a registered trademark of Ortho Pharmaceutical Corp.

BERLEX Dedicated to innovation in OB/GYN medicine

TRI-LEVLEN® 28 Levonorgestrel and ethinyl estradiol
TRI-LEVLEN® 21 tablets–Triphasic regimen

BRIEF SUMMARY
Tri-Levlen®—6 brown tablets, each containing 0.050 mg of levonorgestrel (d(-)-13 beta-ethyl-17-alpha-ethinyl-17-beta-hydroxygon-4-en-3-one), a totally synthetic progestogen, and 0.030 mg of ethinyl estradiol (19-nor-17α-pregna-1,3,5(10)-trien-20-yne-3, 17-diol); 5 white tablets, each containing 0.075 mg levonorgestrel and 0.040 mg ethinyl estradiol; 10 light-yellow tablets, each containing 0.125 mg levonorgestrel and 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day triphasic regimen).

Indications and Usage—Tri-Levlen Tablets are indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OCs) as a method of contraception.

Contraindications—OCs should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5). 8. Benign or malignant liver tumor which developed during the use of OCs or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.
The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with the use of OCs is well established. Three principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OCs are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.
CEREBROVASCULAR DISORDERS—In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.
MYOCARDIAL INFARCTION—An increased risk of myocardial infarction associated with the use of OCs has been reported, confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing myocardial infarction, regardless of whether the patient was an OC user or not. OCs, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a lesser extent.
RISK OF DOSE—In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism, including coronary thrombosis, is directly related to the dose of estrogen used in OCs. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States.
ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES—A large prospective study carried out in the U.K. estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OCs according to age, smoking habits and duration of use. The overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), the risk being concentrated in older women, in those with a long duration of use and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking and duration of use, nor to compare the effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. The available data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. The estimates of risk of death for each method include the combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OCs) plus the risk attributable to pregnancy or abortion in the event of method failure. This latter risk varies with the effectiveness of the contraceptive method. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OCs in women over 40 who smoke. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with OCs increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes or history of preeclamptic toxemia and, especially, by cigarette smoking. The physician and the patient should be alert to the earliest manifestations of thrombophlebitis and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four-to-six-fold increased risk of postsurgery thromboembolic complications has been reported in OC users. If feasible, OCs should be discontinued at least 4 weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization.
PERSISTENCE OF RISK OF VASCULAR DISORDERS—Findings from one study in Great Britain involving cerebrovascular disease and another study in the United States concerning myocardial infarction suggest that an increased risk of these conditions in users of OCs persists after discontinuation of the OC. In the British study, the risk of cerebrovascular disease remained elevated in former OC users for at least six years after discontinuation. In the U.S. study, an increased risk of myocardial infarction persisted for at least 9 years in women 40- to 49-years-old who had used OCs for five or more years. The findings in both these studies require confirmation since they are inconsistent with other published information.
2. *Ocular Lesions:* There have been reports of neuro-ocular lesions, such as optic neuritis or retinal thrombosis, associated with the use of OCs. Discontinue OC medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.
3. *Carcinoma:* Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina and liver. Certain synthetic progestogens, none currently contained in OCs, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case-control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OCs. Of the cases found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time OCs were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only OCs. Several studies have found no increase in breast cancer in women taking OCs or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with OCs, found an excess risk in the subgroups of OC users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of OCs has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with OCs. Close clinical surveillance of all women taking OCs is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use OCs.
4. *Hepatic Tumors:* Benign hepatic adenomas have been found to be associated with the use of OCs. One study showed that OC formulations with high hormonal potency were associated with a higher risk than lower potency formulations. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of OCs. Two studies relate risk with duration of use of OCs, the risk being much greater after 4 or more years of OC use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women taking OCs. The relationship of these drugs to this type of malignancy is not known at this time.
5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring and Malignancy in Female Offspring:* The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence at the present time that OCs further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OCs. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including OCs, in pregnancy. One case-control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OCs, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OCs. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OCs is unknown. It is recommended that, for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period and further use of OCs should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue OCs with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.
6. *Gallbladder Disease:* Studies report an increased risk of surgically confirmed gallbladder disease in users of OCs and estrogens. In one study, an increased risk appeared after 2 years of use and doubled after 4 or 5 years of use. In one of the other studies, an increased risk was apparent between 6 and 12 months of use.
7. *Carbohydrate and Lipid Metabolic Effects:* A decrease in glucose tolerance has been observed in a significant percentage of patients on OCs. For this reason, prediabetic and diabetic patients should be carefully observed while receiving OCs. An increase in triglycerides and total phospholipids has been observed in patients receiving OCs. Three studies have been performed with the Tri-Levlen Tablets (Levonorgestrel and Ethinyl Estradiol Tablets Triphasic Regimen) formulation and no significant alterations in lipid metabolism were noted, with the exception of a slight increase in triglyceride levels in one study. The clinical significance of these findings remains to be defined.
8. *Elevated Blood Pressure:* An increase in blood pressure has been reported in patients receiving OCs. In some women, hypertension may occur within a few months of beginning OC use. In the first year of use, the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure, and in the fifth year of use is two-and-a-half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given OCs. Hypertension that develops as a result of taking OCs usually returns to normal after discontinuing the drug.
9. *Headache:* The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent or severe, requires discontinuation of OCs and evaluation of the cause.
10. *Bleeding Irregularities:* Breakthrough bleeding, spotting and amenorrhea are frequent reasons for patients discontinuing OCs. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary, since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of OCs. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.
11. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.
12. *Breast-feeding:* OCs given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in OCs has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of OCs should be deferred until the infant has been weaned.

Precautions—GENERAL—1. A complete medical and family history should be taken prior to initiation of OCs. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, OCs should not be prescribed for longer than 1 year without another physical examination and PAP smear being performed. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking OCs should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4. OCs may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving OC therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8. Serum folate levels may be depressed by OC therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OCs, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of OC therapy when relevant specimens are submitted. 10. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containing OCs: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

Information for the Patient—See Patient Package Labeling
Drug Interactions—Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.
Carcinogenesis—See "Warnings" section for information on the carcinogenic potential of OCs.
Pregnancy—Pregnancy Category X. See "Contraindications" and "Warnings."
Nursing Mothers—See "Warnings."
Adverse Reactions—An increased risk of the following serious adverse reactions has been associated with the use of OCs (see "Warnings"): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebrai thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, benign hepatomas, congenital anomalies.
There is evidence of an association between the following conditions and the use of OCs, although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.
The following adverse reactions have been reported in patients receiving OCs and are believed to be drug-related: Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally: gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; dysmenorrhea; amenorrhea during and after treatment; temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement and secretion; change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening); intolerance to contact lenses.
The following adverse reactions have been reported in users of OCs, and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, hemolytic uremic syndrome.
Acute Overdose—Serious ill effects have not been reported following acute ingestion of large doses of OCs by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.
Dosage and Administration—To achieve maximum contraceptive effectiveness, Tri-Levlen Tablets (Levonorgestrel and Ethinyl Estradiol Tablets—Triphasic Regimen) must be taken exactly as directed and at intervals not exceeding 24 hours. (If Tri-Levlen is first taken later than the first day of the first menstrual cycle of medication or postpartum, contraceptive reliance should not be placed on it until after the first 7 consecutive days of administration. The possibility of ovulation and conception prior to initiation of medication should be considered.) Any time the patient misses 1 or 2 brown, white or light-yellow tablets, she should also use another method of contraception until she has taken a tablet daily for 7 consecutive days.
For full details on dosage and administration see prescribing information in package insert. 60611-1 5/86

The challenge of change revisited

Presidential address

Frank C. Greiss, Jr., MD
Winston-Salem, North Carolina

In his commencement address to the class of 1988 Thomas K. Hearn, Jr., President of Wake University, made the following statement: "We humans are forever in search of a permanent and unchanging reality, some state of being' to arrest the moving flow of 'becoming' in time. But our efforts to seize and hold a permanent order are in vain. Change is not merely Nature's first law. It is perhaps Nature's only law."

One could deem Dr. Hearn's statement as being so self-evident that it did not need to be said. But if so, consider the following: "The challenge faced by physicians and medical organizations in a world of increasing complexity and change threatens to confuse, bewilder, and overwhelm us. Today we live in a wilderness of new knowledge. It is a challenge to our society as a whole. This challenge of change is vastly greater than at any other time in history because the tempo is so much faster, the social complexities so much more subtle. We must constantly review our methods and traditions in the light of changing knowledge. We must submit to a searching self-analysis to establish the justification for our prejudices."[1] Does not this statement describe, in part, organized medicine's position in 1989? Certainly, but when we consider that it was made 25 years ago by Frank R. Lock, the 29th president of our Association, in his presidential address titled "The Challenge of Change" to the American College of Obstetricians and Gynecologists, it is obvious that Dr. Hearn's reminder did need to be said.

After illustration of how much our perceptions focus on our own memories and our own situations, I will now fall into the same trap and review how vastly greater things may seem to have changed in the past 25 years. In defense of this, I view the rate of change as similar to that of an asymptote, accelerating more rapidly from the abscissa in 1989 than in 1964.

The changes

Although medicine has made dramatic scientific and technologic progress in the past quarter of a century, the changes that have had the most impact on medicine as an institution have been in the attitudinal, social, financial, and ethical spheres.

Attitudinal changes. A general loss of public faith in major institutions in American society has occurred. Not only medicine but education in general, organized religion, government, Congress, the press, the legal profession, and others have experienced this loss of confidence in our nation's leaders and its institutions. This resulted from a series of major events in American life—the Vietnam war, the civil rights revolution, Watergate, the environmental, consumer, and women's liberation movements, the escalation of the national debt of the 1980s, and most recently the advent of leveraged corporate buyouts. Since 1976 medicine's relatively high standing has declined more than in other institutions so that in terms of public confidence we now

rank behind the military and major educational institutions.

High levels of confidence in a particular institution are often associated with three factors: its degree of altruistic behavior and sense of social mission, its level of science, and the degree of nonpolitical behavior it displays. During the past decade there has been little change in our political activity and there has been a marked increase in our scientific knowledge and capabilities. One is left with the conclusion that medicine's declining level of public trust is associated with the growing commercialization of health care, a move away from a traditional image of altruistic behavior and a sense of social mission.

Perhaps of equal importance in changing public perceptions has been a progressive decrease in the value placed on a fundamental American characteristic—personal accountability. Journalist David Brinkley commented on this trend at a United Way luncheon in Winston-Salem, North Carolina, and noted that for the past 50 years the American people have been told by the federal government when things were not going right, "not to worry, we'll fix it for you"; hardly an atmosphere that promotes anything but dependency and an "It wasn't my fault" attitude.

Social and financial changes. Sweeping social and financial changes have occurred in medicine in the past 25 years. They are so interwoven that they must be discussed together. In 1965 Congress passed the Social Security amendments that created Medicare and Medicaid. Organized medicine actively opposed this legislation. After it was passed, physicians not illogically interpreted that the government had said that it would pay for the medical care of our nation's elderly and indigent. Why then should physicians continue to provide free care (perhaps the beginning erosion of our image)? Similarly, institutions like the Kate Bitting Reynolds Health Care Trust in North Carolina diverted hospital supplements for indigent care to other charitable purposes.

It did not take long for Congress to realize they had a tiger by the tail, one getting bigger all of the time because of the increasing cost of medical technology and hospital care. The general inflation rate of the 1970s and the lack of financial incentives to contain costs further accentuated the problem. Between 1965 and 1980 total expenditures increased at an average annual rate of 12.5%, an increase from 5.9% to 9.8% of the gross national product. Federal concern for rising health care costs appeared early in the 1970s through piece-meal legislation. Constraints included mandatory utilization review (1972), an attempt to offer competitive alternatives to fee-for-service practice (Health Maintenance Organization Act of 1974), capital expenditure controls through the Certificate of Need program (1974), and toward the end of the decade, restriction of Medicare payments to levels that were below actual cost. These approaches were largely ineffective and they increased administrative red tape enormously.

In the 1980s there have been implementation of diagnostic related groups to control hospital costs, initiation of second opinion programs, the advent of outpatient and same-day surgery, and increased attention to quality assurance programs, all of which tend to undermine physician-patient relationships. Many would agree that the publication of hospital mortality statistics and the proliferation of peer review organizations and functions have been more divisive than productive.

In 1989 the Hsiao resource-based relative value scale threatens to cap expenditures for physician services as the scenario of expanding Medicare benefits reaches new heights with implementation of the Catastrophic Health Care Bill of 1988. Coverage now extends into the private home, hospice, and nursing home settings and enters the untrodden area of payments for prescription drugs. Those of you who have read the fine print of this bill understand that Congress knows it will be expensive and has passed a significant part of the cost to the recipients. The estimated 40% of Medicare beneficiaries who earn enough to pay federal income taxes will be subject to a surcharge on their taxes up to a maximum of $1050 per person or $2100 per couple in 1993. This represents an unprecedented departure from traditional funding of public programs. For the first time, funding has been transferred within a specific user group to support the poor rather than spreading the cost over the general populace such as occurs with public education or public housing.

On this background, it is not surprising that since 1982 the annual Public Opinion Poll of the American Medical Association[2] has rated cost as the main problem (62% to 68%) that faces health care and medicine in the United States today. However, physician perspectives are changing as a result of a new boy on the street. Whereas 44% to 50% of physicians believed the main problem was cost related in the 1981 through 1984 polls, professional liability was defined for the first time in 1986 as the biggest problem that confronts American medicine. I am certain that many of you in this Association would concur because we as obstetricians-gynecologists have seen the malpractice problem escalate costs, compromise or preclude obstetric care, alter practice patterns, interfere with physician-patient relationships, and most unfortunately have divisive impact within the medical community.

Ethical changes. Time permits but a few comments about the ethical dilemmas presented by social change and scientific progress in our increasingly litigious society. The Supreme Court decision of 1973 that legalized abortion has been soul-wrenching to many and remains controversial. The cases of Karen Ann Quinlan

in New Jersey and Baby Doe in Indiana have been viewed by many as unnecessary legal incursions into family decisions that traditionally have been solved as atraumatically as possible within an acceptable ethic fostered by the physician-patient relationship. In our specialty we have the capability to fertilize anyone's ovum with anyone's sperm and to nourish it to maturity in anyone's uterus. The new ethical problems presented by this technology have already prompted an in-depth study by the American Fertility Society. Perhaps, however, an even greater ethical issue has not been directly addressed. Last year >11% of our gross national product was spent for health care, whereas more than an estimated 35 million Americans were medically uninsured.

Public perceptions

After review of an impressive variety of changes that have impacted on medical practices during the past 25 years, perhaps I should now direct attention to our current public image for it is not all bad in terms of the individual physician.

Physicians. In the average American home, a television set is on 7 hours and 38 minutes of each day.[3] Health-related information occurs many times each hour and there are many physicians. Inasmuch as television presents the most broadly shared images of medical sciences and physicians, we should simultaneously be flattered and concerned by what Americans think they know about physicians. Physicians can solve many problems, even medical. They display infinite accessibility, patience, wisdom, and a lack of material interest. They are authoritative and daring; 40% are engaged in an unusual practice yet to be proven and 13% actually disobey or violate a rule to do something chancy. And they are successful 90% of the time.

This overidealized image of the television physician leads to unrealistic expectations that are reflected in public opinion surveys. A total of 54% of Americans rate physicians high in honesty and ethics. They resent, however, when physicians are not unselfish as they are on television. Half or more also respond that physicians do not explain things well, do not care as much as they used to, do not charge reasonable fees. They also believe that people are beginning to lose faith in physicians. However, the negative feeling Americans express toward physicians to surveyed items are not unusual—they feel that way toward many other professionals as well. In relative terms, the public image of physicians is quite good. In the April 1986 survey of the National Opinion Research Center, 46% of people had a great deal of confidence in those who run medical institutions—No. 1 in comparison with other institutions.[2]

Professional liability. The public is increasingly cognizant of a general liability crisis and a substantial majority is now sympathetic with physicians on a number of specific issues related to malpractice insurance and lawsuits. A total of 67% of people believe physicians have to pay too much for malpractice insurance and between 43% and 50% think that people who file malpractice suits are just looking for an easy way to make money. Between 56% and 70% think there should be a limit on the amount of money that can be awarded to someone who sues because of malpractice, 79% favor setting limits on lawyer's fees in large awards, and 41% to 59% think jury awards are too high.

Problems facing medicine. In the 1986 American Medical Association Survey, >63% of the public believed that cost is the main problem that faces medicine today, exceeding other considerations by 50%. Paradoxically, the public will press for more health care, not less. A similar paradox exists in how Americans view their own health care. On one hand, they are highly critical of the U. S. health care system as a whole; on the other hand, most people are highly satisfied with the health care they receive. Americans are not in favor of giving up their personal physicians for care delivered by low-cost physician groups. However, they are enthusiastic about requiring low income persons to use less costly clinics or health maintenance organizations.

Our position in 1989

The foregoing should reassure today's physicians. Our greatest ally, the public, is basically supportive of their own health care and is generally sympathetic to their physician's problems. Although the public perceives the problem of cost, it desires increased care, and it defers the solution of the blight of the poor to the government. The government, on the other hand, is faced with a continuing budget deficit and the largest national debt in history. Because many would consider it to be political suicide to cap services, our legislatures are increasingly shifting the onus to the health care delivery system. And oftentimes physicians find themselves caught in the middle. Government policies of reactive rationing, as opposed to prospective allocation, daily threaten physicians as they attempt to cope with the complexities of cost control and quality assurance, the specter of malpractice, and the difficult task of monitoring physician activities in the office, in hospitals, and in the courts. Perhaps most threatening is the relative lack of input physicians have had in dealing with these problems for traditionally, medicine is used to "calling the shots." We have yet to come to grips with the fact that society is challenging a major tenet of our professionalism, its autonomy. Let us digress for a moment and consider this professionalism of ours.

Professionalism. All of us know or think we know what professionalism is and all of us think we are professionals. However, when I asked a number of people about the elements comprised by professionalism,

I was surprised how difficult it was for them to verbalize a consistent group. This prompted me to go back to the Oxford English Dictionary in which any one of a number of definitions could be found. My own biases led me to select one attributed to Maurice in 1839: "that kind of business which deals primarily with men as men, and is thus distinguished from a trade which provides for the external wants or occasions of men."[4] Such a definition is obviously vague in terms of the description of the elements of professionalism. In 1915 Abraham Flexner espoused more definitive criteria[5] and in 1987 Reed and Evans[6] described components of professionalism that embody those described by Flexner but put them in more currently applicable terms. Those that I think are pertinent to our discussion are as follows: (1) the members of the profession determine its standards of knowledge and expertise, (2) the profession is given authority to license practitioners by state boards made up largely of members of the profession, (3) social policy and legislation that relate to the profession are heavily influenced by members of the profession, (4) a profession has a code of ethics that governs practice, the tenets of which are more stringent than legal controls, (5) a service orientation supercedes the proprietary interest of professionals, and (6) a profession is largely free of lay control with its practitioners exercising a high degree of occupational autonomy.

Reed and Evans[6] point out that professional autonomy subsumes most of the other preconditions of professionalism and that autonomy and professionalism are crucially linked, such that when slippage in a profession's autonomy occurs, the profession itself is threatened. This is what has happened during the past quarter of a century. Changes in societal attitudes and demands have taken autonomy away from the medical profession in areas of the establishment of social policy, infringement on ethical issues, monitoring physcian and hospital practice, and the challenge of medical practice through the mechanism of malpractice litigation. This slippage in our autonomy, combined with the pervasive and inseparable influence of financial factors, has induced apathy and a sense of self-pity within the medical profession.

The future

There is no panacea and it is evident that the forces and systems that have evolved over the past 25 years will not change rapidly. However, I think that medicine as an institution must realistically assess its current situation and expend its efforts in ways and directions that will not only improve our public image but will have the greatest likelihood to achieve the goal of easily accessible, high quality, affordable medical care for all citizens. Virtually all recent health legislation has been patchwork to address short-term problems with quick fixes. None has addressed a consistent long-term policy. When we consider our political system with its changing leadership every 4 to 8 years and its sensitivity to special interest groups, this should not be a surprise. To really influence long-term health policy, a coalition that represents all of the players from the consumers to the payers to the providers must be developed that will be an objective sustaining force with sufficient clout to influence legislation from the broad societal view. Such a coalition, the North Carolina Institute of Medicine, has been in existence since 1983. Originally supported by the Kate Bitting Reynolds Health Care Trust, it now has state legislative dollars as well. Its members are drawn from leaders in government, education, business, industry, the health and legal professions, the hospital and health insurance sectors, and the public at large. Because of its broad membership base without a majority from any single professional or special interest group, it can objectively represent the public interest on health-related public policy issues. Already a number of health policy concerns that range from indigent care to cost containment to medical malpractice insurance have been identified and of particular interest to members of the Association, the first task force to reduce infant mortality and morbidity in North Carolina has completed its deliberations. To fully appreciate the potential of such an Institute, particularly as it applies to medicine, one must understand the process involved in the achievement of consensus. Initially this involves exchange of information. Problems within the medical profession as well as those that involve multiple constituencies are identified and solutions are developed on the basis of objective unbiased data. Common goals are identified and means to those ends are planned. In this process, medicine maintains its traditional role of advocacy for quality basic health care to all at a reasonable cost. And when physicians have taken leadership in efforts to control costs, not only is their credibility and public image improved, but there is a greater potential for physicians to retain professional satisfaction than when controls are imposed from the outside. It is critical to understand that the Institute of Medicine is not a lobbying force per se. However, by virtue of its diverse membership, each with organizations and contacts, a potentially huge lobbying force can be developed. In effect, medicine lets the others do the lobbying for itself.

The Institute I have described is unique among the states and its impact remains unproven. However, it is supported by the state legislature, its influence is growing, and the process is one that clearly provides significant input from the medical profession. All of you are aware of similar although not as comprehensive coalitions at community levels. In general, their information base is small and they have little clout, as compared

with the potential of a statewide organization. However, I encourage all of you to become active participants because mutual understanding is inevitably improved and this is the basis on which progress is made.

As we influence the implementation of a health delivery system that provides affordable and uniform quality of care, we must stop protecting the old ways. We must accept change and deal with it positively if the public is to maintain its trust in the medical profession. We must understand how we got to our present position and the current forces that impact on it. We must remain united for otherwise we lose our effectiveness. We must understand that government and business really do not want to run medicine unless there is a void. We must maintain our commitment to service, especially the medically indigent, and we must understand that in the eyes of the public, curing is not synonymous with caring. Finally, I remind you that the greatest reward we physicians have is the satisfaction of improving the quality of life of our fellow man. Our professionalism and especially our altruism must remain pervasive for if we surrender our obligations to legislative and commercial forces, who will remain the public's unbiased medical advocate?

Effects of terbutaline sulfate on fetal cardiac function

Ruth Petersen, MD, Laurence S. Carter, BS, Nancy C. Chescheir, MD, Vern L. Katz, MD, and Robert C. Cefalo, MD, PhD

Chapel Hill, North Carolina

An isolated heart preparation was used to study the effects of terbutaline sulfate (Brethine) on fetal cardiac function. Pregnant guinea pigs received daily subcutaneous injections of terbutaline for 10 day, whereas a control group received placebo injections. Fetal guinea pig hearts were evaluated for cariodynamic and pathologic differences. Fetuses exposed to terbutaline demonstrated a higher mean heart rate ($p < 0.01$), a higher mean heart weight ($p < 0.05$), a higher mean heart weight/body weight ratio ($p < 0.01$), and a trend toward higher left ventricular systolic pressure levels ($p < 0.1$). These hemodynamic responses in fetuses exposed to terbutaline may result in increased functional demands that may predispose myocardial tissue to damage. (Am J Obstet Gynecol 1989;161:509-12.)

Key words: Terbutaline sulfate, β-sympathomimetic drugs, fetal effects, fetal guinea pig heart, heart preparation

β-Sympathomimetic therapy has become a popular tocolytic agent for preterm labor. However, various maternal and fetal cardiovascular side effects must be balanced with the therapeutic advantages of a drug like terbutaline sulfate. Maternal effects include an increase in heart rate and systolic pressure,[1] an increased risk for pulmonary edema, and electrocardiograph changes consistent with myocardial ischemia.[2-4] Animal studies have shown fetal myocardial tissue damage after administration of β-sympathomimetic drugs both in vivo[5] and in vitro[6] as well as organ weight changes, notably cardiomegaly, in rabbit fetuses chronically exposed to tocolytic agents (unpublished observations). Postmortem examination that indicate changes consistent with myocardial infarction have been reported for human

infants chronically exposed to β-sympathomimetic drugs.[7,8] We studied fetal cardiac function and pathologic changes after chronic terbutaline therapy in the pregnant guinea pig.

Method and materials

This project was approved by the Committee on Animal Research at the University of North Carolina and all care and procedures were within their guidelines. Animals were given food and water as desired. Pregnant Hartley guinea pigs (1.1 to 1.36 kg, from Charles River Breeding Co, Waltham, Mass.) were randomly divided into two groups 11 days before estimated partus (normal gestation period = 65 days). The study group was given subcutaneous injections of 0.03 ml (1 mg/ml) of terbutaline sulfate (Brethine) with 0.04 ml of saline solution twice a day. This dose approximates the suggested therapeutic daily dose of terbutaline as a tocolytic agent for human beings on a weight basis. The control group was given 0.07 ml of saline solution subcutaneously twice a day.

One or two days before estimated term, the pregnant guinea pigs were anticoagulated with 1000 U of heparin intraperitoneally and anaesthetized with ether. The fetuses were removed and the hearts from two pups per litter were rapidly excised and placed in an ice-cold 0.9% saline solution. Almost immediately, the aortic root of the heart was secured to an 18-gauge needle and attached to a modified Langendorff apparatus (Fig. 1). The isolated fetal hearts were perfused with a Krebs-Henseleit solution that consisted of sodium chloride 118.5 mmol, sodium bicarbonate 25.0 mmol, dextrose 5.5 mmol, potassium chloride 4.4 mmol, calcium chloride 1.3 mmol, potassium monobasic phosphate 1.2 mmol, and magnesium sulfate 1.2 mmol. With the initiation of retrograde perfusion, the aortic valve closed and thereby channeled all the perfusion medium, aerated with 95% oxygen and 5% carbon dioxide, into the coronary arteries. Coronary flow was measured with a graduated cylinder and stopwatch as it exited the heart chamber (Fig. 1). Aortic perfusion pressure was maintained between 60 to 65 mm Hg. The perfusates entering and surrounding the heart were warmed by a water-jacketed system to 37° C.

A miniature latex balloon tip catheter filled with saline solution was inserted into the left ventricle through the mitral valve to measure fetal cardiac dynamics. Fetal heart rate (FHR), left ventricular systolic and end-diastolic pressures (maintained at 6 mm Hg) were continuously measured with the ventricular balloon. These data were recorded on a Hewlett-Packard 7754B four-channel system (Palo Alto, Calif.). From this, contractility, measured by the ratio of dP/dt, was determined from the slope of the left ventricular pressure waveform. Three electrodes that formed an Einthoven triangle were placed into the heart chamber to allow measurement of the PR, QRS, and RR intervals through this electrocardiogram configuration.

After initiation of aortic perfusion, placement of the left ventricular balloon and electrocardiogram electrodes, the hearts were allowed a 20-minute equilibration period. Readings of FHR, left ventricular systolic pressure, coronary flow, dP/dt, aortic perfusion pressure, and PR interval were taken at 20, 30 and 60 minutes.

Fetal hearts not used in the heart preparation and maternal hearts were extensively studied histologically with hematoxylin and eosin stain.

Differences between groups at 60 minutes were measured with the Student t test for unpaired observations. The p values <0.05 were statistically significant.

Results

From the seven pregnant guinea pigs that received terbutaline, 11 fetal hearts were evaluated with the isolated heart preparation. Eight fetal hearts from four pregnant guinea pigs injected with saline solution served as controls.

Table I lists fetal parameters measured including body weight, heart weight, FHR, left ventricular systolic pressure, coronary flow, dP/dt, and PR interval. Values are included for the control group ($n = 8$) and the group treated with terbutaline ($n = 11$). Fetuses in the group exposed to terbutaline showed a significant increase in FHR ($p < 0.01$) and fetal heart weight ($p < 0.05$), and a significant decrease in the PR interval ($p < 0.05$) relative to the control fetal values. In addition, there is a trend toward a higher left ventricular systolic pressure level ($p < 0.1$) for the treated fetal hearts.

Through evaluation of maternal and fetal body weights, heart weights, and litter size for the treated and control groups, the ratio of heart weight/body weight was found to be significantly greater ($p < 0.01$) for the treated fetal guinea pigs, compared with the controls. No similar difference existed between the treated mothers and control mothers.

Grossly, there were no identifiable differences in the fetal hearts of the treated group and the control group. Histologic examination of seven treated fetal hearts, and four control fetal hearts, and the maternal hearts did not reveal any evidence of myocardial necrosis. Ventricular dilation of one fetal heart in the treated group was seen.

Table I. Fetal weights and cardiodynamic measurements in control and terbutaline study groups

	Control ($n = 4$)	*Terbutaline ($n = 11$)*	*p Value*
Body weight (gm)	73 ± 3	78 ± 6	NS
Heart weight (mg)	325 ± 18	401 ± 31	<0.05
FHR (beats · min^{-1})	198 ± 4	228 ± 6	<0.01
Left ventricular systolic pressure (mm Hg)	42 ± 3	52 ± 4	<0.1
dP/dt (mm Hg · sec^{-1})	767 ± 57	870 ± 76	NS
Coronary flow (ml · min^{-1})	8.1 ± 0.4	8.0 ± 0.5	NS
PR interval	75 ± 4	63 + 2	<0.05
Heart weight/body weight × 100	0.446 ± 0.010	0.517 ± 0.015	<0.01

Comment

In the measurement of fetal cardiac parameters in the animals exposed to terbutaline, the effects of repeated administration of betamimetic drugs are noted through a higher mean heart rate and a trend toward a higher left ventricular systolic pressure level. An increase in both of these parameters results in a higher cardiac work load and a higher myocardial oxygen demand. As demonstrated by the fetuses exposed to terbutaline, adaptive responses to such chronically increased functional demands may lead to ventricular dilation and to a proportionately higher heart weight, suggestive of cardiac hypertrophy. The fact that fetal heart weight/body weight ratios in the treated group were higher than in the control group illustrates the possible hypertrophic response of the cardiac muscles exposed to chronic work loads.

As with any chronically stressed heart, there is a chance for eventual decompensation. The increased metabolic requirements placed on the fetal hearts exposed to betamimetic drugs, even with these minimal doses, may predispose these hearts to ischemia and infarction as myocardial tissue requirements exceed available supply. Explanations for our lack of microscopic myocardial damage may be related to the fact that we treated our animals with minimal therapeutic doses, unlike other investigators who approached much higher levels of β-sympathomimetic drugs.[5] Of importance is that even with these minimal doses we have demonstrated responses to β-sympathomimetic drugs are similar to those that predispose any myocardial tissue to acute and possibly lethal damage.

The decision to use long-term treatment with tocolytic agents requires the knowledge of both long-term and short-term maternal and fetal effects. We emphasize the importance of considering the impact such long-term treatment with tocolytic agents has on the fetal cardiac function. If β-sympathomimetic drugs are used chronically for tocolysis, these fetuses should be followed up carefully in utero for signs of decreasing or impaired cardiac function, such as tachycardia or fetal hydrops.

We thank Dr. F. G. Dalldorf for his assistance in the histologic review of our slides.

Discussion

Dr. E. O. Horger III, Charleston, South Carolina. I offer my congratulations to Dr. Petersen and her associates for a very nice investigation of the effects of terbutaline sulfate on fetal cardiac function, for her winning the John R. McCain Student Fellowship Award, and for her presentation.

β-Sympathomimetic drugs are the most frequently used tocolytic agents. Whereas side effects of β-sympathomimetic therapy are not uncommon, they are usually well-tolerated. On the other hand, some side effects are potentially quite dangerous. Reported maternal hazards chiefly involve cardiovascular and metabolic problems including pulmonary edema, myocardial ischemia, arrhythmia, hyperglycemia, and hypokalemia. Cardiovascular side effects have been reported to occur in as many as 5% of these patients. Reported fetal and neonatal complications of note include cardiac toxicity and ischemia, hypoglycemia, hypocalcemia, and ileus. Although focal myocardial necrosis and fatty degeneration have been reported in the hearts of newborns whose mothers had been treated with β-sympathomimetic drugs, there has been no proof that such heart lesions were responsible for neonatal deaths.

Dr. Petersen and her associates studied the effects of terbutaline on cardiac function, weight, and histology in fetal guinea pigs after chronic maternal administration of terbutaline. Their findings included significant increases in heart rate and heart weight, a trend toward increasing left ventricular systolic pressure, and an absence of histologic changes.

Two important questions must be answered for those of us who use terbutaline and other β-sympathomimetics in the treatment and prevention of premature labor. First, why do these cardiac manifestations occur? And second, what is the real risk to the human fetus after the mother is treated with terbutaline? β-Sympathomimetic stimulation certainly increases heart rate in both mothers and fetuses, which generates an increased requirement of the myocardium for metabolic substrates. As the increased functional demands continue, myocardial hypertrophy occurs in response to the increased work. If the substrate demands exceed the supplies, the potential for myocardial ischemia certainly exists. This potential may be compounded by other factors that act in the situation of premature labor, such as hypoxia, acidosis, fever, and corticosteroids.

No histologic evidence of myocardial necrosis was found in the guinea pig fetal hearts. Possible explanations for this may lie in the duration of terbutaline treatment or in the dosage used. The guinea pigs were treated for the last 9 or 10 days of pregnancy, a span that runs approximately 14% to 15% of the guinea pig pregnancy. A similar proportion of human pregnancy would run 5 to 6 weeks, and we only infrequently manage to use β-sympathomimetics for such a long period of time. It was noted that the dosage used in the guinea pigs was low but approximated the suggested tocolytic dose of terbutaline for human beings. The guinea pig study used approximately 50 μg/kg terbutaline per day subcutaneously. Although this does run approximately equal to the recommended subcutaneous dosage in human beings, chronic administration in human patients is not continued subcutaneously. The usual oral dose in human patients runs considerably higher at approximately 200 to 400 μg/kg per day, but results in lower peak serum concentrations. The influence of these factors on fetal myocardial lesions has not been determined.

The risk to the human fetus cannot be answered by Dr. Petersen's study. Although other studies have shown similar changes in the hearts of human fetuses and newborns, the significance of these findings remains very uncertain. Nonetheless, the possibility is rather frightening.

Analysis of fetal loss after transcervical chorionic villus sampling—A review of 719 patients

Ronald V. Wade, MD, and S. Robert Young, PhD
Columbia, South Carolina

Chorionic villus sampling was performed under real-time ultrasonographic direction on a study group of 719 patients from September 9, 1985, through May 5, 1988. Follow-up of 714 of these patients who would have reached 28 weeks' gestation on September 1, 1988, revealed "an unintended" abortion rate of 4.1% by 20 weeks' gestation. Nine patients had a fetal loss <4 weeks after the procedure; 19 had losses up to 12 weeks after the procedure and before 20 weeks' gestation. This study revealed a significantly increased risk of fetal loss with an increase in the number of catheter insertions ($p < 0.001$). The risk of fetal loss after one sampling attempt was 3%, 7.8% after two attempts, and 14.3% after three attempts. (AM J OBSTET GYNECOL 1989;161:513-9.)

Key words: Chorionic villus sampling, spontaneous abortion, prenatal diagnosis, fetal loss

The safety of first-trimester fetal cytogenetic diagnosis by transcervical chorionic villus sampling is a matter of continued concern. The risk of the procedure is thought to be low, but it is difficult to delineate because of the methodologic problems in the establishment of the background loss rate in a comparable group of women.[1]

This analysis reviews multiple variables of patients who had fetal loss after transcervical chorionic villus sampling during the study period. The risk of the sampling procedure is assessed and the apparent pathophysiologic mechanisms of fetal loss are tabulated. The purpose of this study is to characterize specific determinants of increased fetal risk before the third trimester in women who undergo transcervical chorionic villus sampling. Ultimate pregnancy outcome and third-trimester pregnancy performance will constitute a separate publication at a later date.

Material and methods

Ultrasonography-directed transcervical chorionic villus sampling was performed on 719 patients in the Department of Obstetrics and Gynecology of the University of South Carolina School of Medicine and Richland Memorial Hospital between September 9, 1985, and May 5, 1988. Approval was obtained from the Institutional Review Committee of Richland Memorial Hospital and the Ethics Committee of the School of Medicine of the University of South Carolina to offer this method of first-trimester prenatal diagnosis. Follow-up data were obtained on 714 patients (99.3%) by direct patient and physician contact. The study group was defined as all patients with an estimated gestational age ≥28 weeks by September 1, 1988.

All chorionic villus sampling procedures were performed by a single physician (R. V. W.) with transabdominal real-time ultrasonography with guidance by either an Ultramark IV (Advanced Technology Laboratories, Inc., Bothell, Wash.) or a 4000 S/L (Advanced Diagnostic Research, Inc., Bothell, Wash.) ultrasound scanner with a 3.5 MHz transducer. Fetal gestational age was determined by fetal crown-rump length measurement according to the method of Robinson and Fleming.[2]

The cervix and vagina were cleansed with povidone-iodine solution and all samples were obtained by a polyethylene 16 gauge catheter (Intracath-Deseret Medical, Inc., Sandy, Utah) over a surgical wire stylet. If more than one attempt was required, the catheter and the operator's gloves were changed. Genital herpes virus infection or allergy to povidone-iodine were contraindications to performance of the procedure. The procedure was terminated after obtainment of an adequate volume of villi for diagnostic studies (>10 mg by visual estimate), after three attempts, or at the patient's request to discontinue the procedure.

The fetal losses were reviewed to determine the time interval from performance of the sampling procedure to fetal loss and were classified into groups as early, late, or remote. An early loss is defined as ≤4 weeks after the procedure; a late loss is defined as >4 weeks but ≤12 weeks after the procedure; and remote is defined as >12 weeks but ≤20 weeks after the procedure.

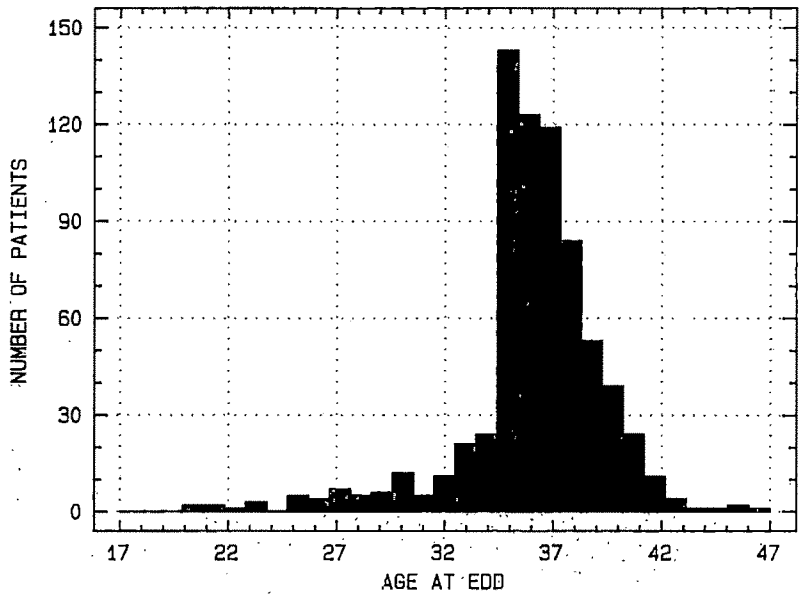

Fig. 1. Frequency of maternal age at time of estimated date of delivery (n = 714).

Table I. Mechanism of fetal loss by time interval from procedure to loss

Mechanism	*Early* $n = 9$	*Late* $n = 19$	*Remote* $n = 3$
Fetal death in utero	4	13	1
Spontaneous abortion	4	3	1
Septic abortion	1	0	0
Premature rupture of membranes	0	3	1

An effort was made to establish the underlying mechanism of fetal death.

All patients who had a fetal loss were analyzed by multiple criteria including maternal age, gravidity, estimated gestational age, quantity of the sample obtained, and number of sampling attempts. Particular emphasis was placed on review of the impact of multiple aspiration attempts, fetal karyotype, and volume of villi removed. The specific genetic findings and karyotype analysis are not evaluated in this study, but will be the subject of a future publication. In this study "abnormal karyotypes" refer to recognized aneuploidic conditions of clinical significance.

Continuous parameters were subjected to statistical tests by Student t test with results as mean ± SD. χ^2 analysis with Yate's correction was used to compare groups in two-by-two contingency tables. A p value <0.01 was considered to be significant. Tests for significance were performed and supported by Statgraphics (STSC, Rockville, Md.) and PC Statistician (Human Systems Dynamics, Northridge, Calif.) computer statistical software packages.

Results

Of the 719 patients who underwent chorionic villus sampling, 87% were at risk for fetal aneuploidy because of advanced maternal age. Age distribution is shown in Fig. 1. Of the 714 patients available for follow-up, 29 elected to interrupt their pregnancies for various reasons including abnormal karyotype, anencephaly, single gene defect, or other congenital conditions. A total of 20 patients (2.8%) had clinically abnormal karyotypes. An additional 20 patients had other cytogenetic findings such as balanced translocations and heterochromatin, but were included as "normal" patients in this analysis.

A total of 685 patients continued their pregnancies and formed the base study group for risk assessment. Fetal loss occurred before the beginning of the third trimester in 31 patients (4.5%); 28 (4.1%) of these patients had fetal loss before 20 weeks' gestation. Of the losses, nine were classified as early losses, 19 as late, and three as remote. The maximum gestational ages achieved by these groups were 16, 20, and 26 weeks, respectively. Table I indicates the mechanism of these losses.

Comparison of those patients with fetal losses to those who had no loss showed no significant difference for the parameters of maternal age, gravidity, quantity of villi aspirated, and gestational age, as shown in Table II. In addition, there was no difference between the group of patients who had fetal loss and those who had early, late, or remote losses when evaluated for these same variables by groups of one, two, or three sampling attempts. The mean number of catheter insertions dif-

Table II. Comparison of patients and procedural characteristics between those with continuing pregnancies and those with losses

fered between the control group without fetal loss and the loss groups (Table III). χ^2 analysis of the data in Table IV reveals an increasing risk of fetal loss with multiple attempts ($\chi^2 = 14.8914$; $p = 0.0006$). With one attempt, the risk as measured by relative frequency of a subsequent loss was 0.03 or 3%. After two attempts the risk rose to 0.078 or 7.8%, and at three attempts became .143 or 14.3%. When comparison was made of one attempt and two attempts, there was no significant difference ($p = 0.03$); significance was achieved when comparison was made of one attempt and three attempts ($p = 0.0017$). The significance level that reflects the increase in risk from two attempts to three attempts was weak at $p = 0.36$.

The proportion of abnormal karyotypes was not significantly different in those patients who had one, two, or three sampling attempts. Only three patients requested that the procedure be terminated. All of these requests were made after the first attempt and were secondary to cervical pain. Two patients who had previous cervical cryosurgery had severe pain when the catheter traversed the endocervix. In one patient an appropriate volume of villus tissue was obtained for diagnosis, in the other patient insufficient tissue was obtained. The third patient refused a second attempt because of the necessity of cervical traction with an Allis clamp.

The apparent lack of influence of operator experience on the frequency of the overall loss rate is shown in Table V. Of interest however, 36 of the 42 patients who had three sampling attempts occurred in the first 411 patients (i.e., subgroups 1 to 3). The six losses in the group of patients who had three attempts were distributed as follows: two losses in the first group, patients 1 to 137; three losses in patients with sequence numbers 275 to 411; and one in the last group with sequence numbers 549 to 685.

One patient had an obvious subchorionic bleeding episode then progressed to spontaneous abortion within 48 hours after the procedure. Another patient was seen 72 hours after the procedure with an incomplete abortion and had an oral temperature of 99.8° F. Both of these patients had one catheter insertion. The remaining early losses were characterized by silent fetal death or spontaneous abortion >7 days after the procedure. Women in the late group were more likely to have in utero death or premature rupture of the membranes.

Table III. Comparison of the number of catheter insertions between the control group without loss and the fetal loss groups by time interval from procedure to loss

Group	*Insertions*	*p Value**
No loss ($n = 654$)	1.27 ± 0.56	
Early loss ($n = 9$)	1.89 ± 0.78	0.001
Late loss ($n = 19$)	1.58 ± 0.77	0.018
Remote loss ($n = 3$)	1.67 ± 1.15	0.220

Data are mean ± SD.
*Student t test.

After an uncomplicated postprocedure course, three cases in the group with late loss had severe oligohydramnios, elevated maternal serum α-fetoprotein levels, and fetal death. The pathophysiology in these patients is uncertain. In none of these cases was there a history consistent with overt amniorrhexis, but two of the three patients did have prolonged bleeding near the time of fetal death, with the blood loss noted to be dark bloody fluid. In none of these patients was subchorionic hematoma noted by ultrasonography. All of these fetuses had normal renal development at postmortem examination.

Comment

Chorionic villus sampling continues to emerge as an increasingly acceptable means of fetal cytogenetic diagnosis in the first trimester.[3, 4] Many studies have detailed institutional experiences with this procedure, and reported loss rates from 1.9% to 5.8%.[3-9] Few studies to date have provided comprehensive follow-up on patients who undergo chorinoic villus sampling. This

analysis of 714 pregnancies that would have completed 28 weeks' gestation after transcervical chorionic villus sampling focuses on the risks of the procedure and the effect of the risk estimate on appropriate patient counseling.

The absolute increase in fetal loss after chorionic villus sampling is difficult to establish because of the problems involved with the definition of a comparable control group and background spontaneous abortion rate. The impact of the increase abortion rate as a function of maternal age must be considered. Several studies have been published in an effort to establish the background loss rate of ultrasonographically normal pregnancies at 8 to 12 weeks' gestation.[10-13] The overall loss rates in these studies have been noted to be in the 2.0% to 3.2% range. When corrected for maternal age in women older than 35 years, however, the spontaneous abortion rate up to 20 weeks' gestation is in the 4.3% range.[13] Comparison of losses after chorionic villus sampling with groups of women who have ultrasonographic scans at 8 to 12 weeks' gestation without instrumentation also ignores the spontaneous abortion of aneuploidic fetuses in the comparison group and the impact of elective interruption of aneuploidic pregnancies in the study group. Theoretically a randomized study is needed with a control group for women older than 35 years who did not undergo prenatal diagnosis, but such a study is not feasible at this time.

Comparison of the fetal losses in this study with a published transabdominal chorionic villus sampling study that reported a fetal loss rate of 3.2% reveals no significant difference in risks ($\chi^2 = 0.118$).[14] Large studies of transabdominal sampling should be reported to allow a more accurate comparison of the two methods.

Although data exists with regard to placental site, there is no information with regard to the position of the uterine fundus relative to the median axis of the pelvis (i.e., anteverted or retroverted). The placental site was therefore not evaluated as a potential variable because the important relationship is that of placental site relative to the position of the uterine fundus and accessibility through the endocervix.

It is difficult to define the impact of operator experience on the subsequent fetal loss rate from these data for two reasons. First, an extensive practice series of patients who requested elective pregnancy interruption (>100 samples) was perfomed by this team before institution of this series of ongoing pregnancies. Second, although the frequency of three insertions was greater in the first half of this series, the losses in these patients who underwent three sampling attempts was more evenly distributed. The latter fact must be viewed with caution, however, because of the few patients involved. The likelihood of a type II statistical error is significant when analyzing a loss group of only six patients.

The procedure-related loss rate is an extremely important statistic that should form the foundation of patient counseling. These data would suggest that patients should be informed of an increasing risk of fetal loss that reaches significance at three attempts. Reassessment of the maternal risk and the advisability of amniocentesis for diagnosis should be discussed if two sampling attempts do not provide an appropriate volume of villi for analysis (Fig. 2). Nonetheless, with the use of the spontaneous background rate of 4.3% in the group older than 35 years, the loss rate of 4.1% in our study group up to 20 weeks' gestation (28 losses out of 685 patients) compares favorably (Fig. 3). It would appear that the procedure-related risk in patients who had one catheter insertion is extraordinarily small and, indeed, may be negligible. Two insertions result in a loss rate higher than background, and three insertions further increase the risk of fetal loss. The loss rates of

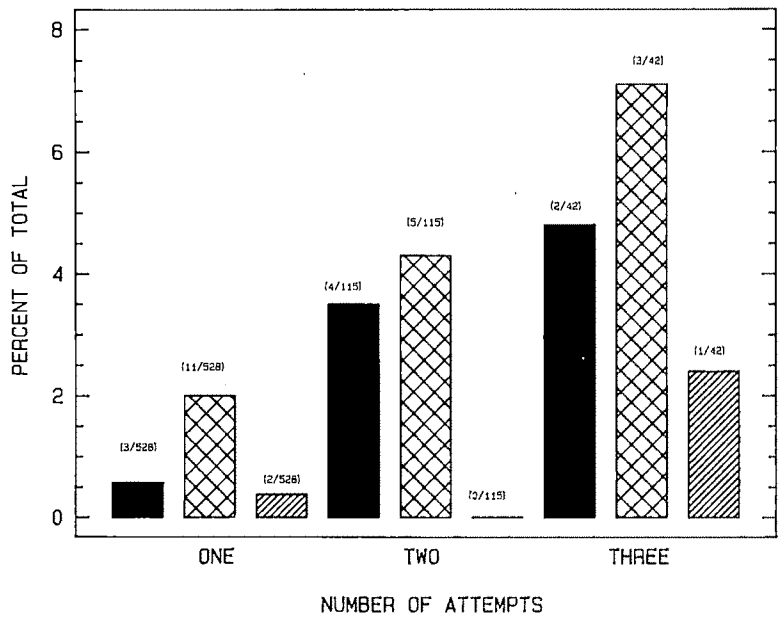

Fig. 2. Fetal losses as function of number of catheter insertions (attempts) expressed as percentage of total attempts. *Solid bar* indicates early loss; *cross-hatched bar* indicates late loss; *right diagonal bar* indicates remote loss.

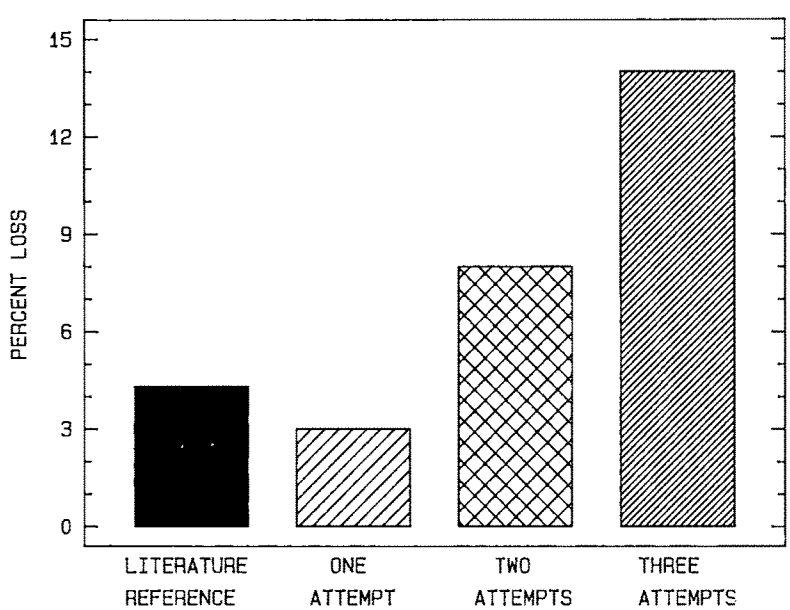

Fig. 3. Percentage of fetal loss expressed as function of catheter insertions (attempts) compared with background spontaneous loss data of Wilson et al.[13]

3% after one attempt, 7.8% after two attempts, and 14.3% after three attempts conform favorably to other studies that address this concern.[1, 8]

The designation of a particular fetal loss as "procedure related" or "not procedure related" is frequently speculative; pathophysiologic mechanisms responsible for fetal loss after chorionic villus sampling are clinically difficult to ascertain. Subchorionic hemorrhage appears to be the most obvious mechanism, but many losses remain idiopathic. Definition of a high-risk group is therefore difficult. However, it would seem prudent to approach with caution patients who have notable early pregnancy bleeding or subchorionic hematoma formation noted by ultrasonography before the procedure.

At the present time the explanation of the causes of

maternal serum α-fetoprotein levels elevated, oligohydramnios, and fetal death is unclear. This association of findings has been reported in noninstrumented pregnancies with a high incidence of renal abnormalities noted.[15] There was no perceptible loss of amniotic fluid in this group of patients but an imperceptible loss of fluid or other possible causes of placental failure as has been suggested by others as a possible mechanism of this symptom complex cannot be excluded.[16]

In summary, these data imply that much of the procedurally related risk of fetal loss after chorionic villus sampling may be a function of the number of catheter insertions with a significantly increased risk of fetal loss in those patients who have more than two sampling attempts. Counseling of patients should reflect this increase in risk.

Discussion

Dr. George W. Cornell, Suffolk, Virginia (Official Guest). Since the introduction about 20 years ago of chorionic villus sampling as a tool for prenatal diagnosis of genetic and enzymatic fetal defects, there has been a persistent problem in the establishment of the safety of the procedure relative to amniocentesis and a background of spontaneous fetal wastage. A number of studies have been published that address this problem, and the present study adds to the entire body of knowledge on the subject.

This study benefits from its large sample size, good follow-up, and clearly defined parameters. The central point of the study is that the risk of the procedure increased with the numer of attempts, and is significantly increased when one versus three attempts are compared.

It would seem logical that operator experience would have a beneficial effect on sampling outcome and this has been suggested to be the case in some studies.[1] The present study, however, clearly shows that this is not the case. It also shows that maternal age does not affect the outcome. This is in contrast with a study from The Netherlands[2] that showed a statistically significant increase in risk with advancing maternal age, but not with the number of samplings. An earlier study[3] suggested that sampling was safest in gestational weeks 9 through 11, a finding not supported by the present study. Gravidity and quantity of villi aspirated are not shown to be statistically significant. A procedure-related loss of $<1\%$ is suggested, which agrees with loss rates in other studies.

A large randomized multicenter study[4] compared chorionic villus sampling at 9 to 12 weeks' gestation amniocentesis at 15 to 17 weeks' gestation. The results, although not statistically significant, suggested that the potential difference in loss rates between the two methods was not more than 2.4% for women ≥ 35 years of age. There was an unexplained tendency to later losses in the chorionic villus sampling group.

It is readily apparent from the literature that the original question of exactly what the risk of chorionic villus sampling is compared with amniocentesis and background loss is still now answered. In fact, it may never be answered because such a study would require that some study patients be randomized into a group in which nothing is done, which raises grave ethical concerns.

Transcervical chorionic villus sampling is more difficult when the placenta is in certain locations. The present paper does not correlate the number of attempts with placental location. This would be an interesting comparison. It might be possible to use transabdominal chorionic villus sampling technique on selected placental locations to further reduce fetal loss and thereby increase the safety of the procedure.

DR. WADE (Closing). I thank Dr. Cornell for his thoughtful comments, and I will elaborate on two aspects of his discussion.

First, the lack of a demonstrable effect of operator experience on the loss rate may be partially explained by the fact that the operator had performed >100 practice aspirations on >50 patients before beginning the series of patients with continuing pregnancies reported here. Second, these data included the location of the implantation site of the placenta, but did not include the relative position of the uterine fundus to the median axis of the pelvis. The most important relationship deals with the accessibility of the implantation site and therefore is a function of the relative implantation site orientation to the internal cervical os. We do not have data on the position of the uterine fundus in this data base. For this reason, placental location as a potential variable was not included.

The lack of impact of gestational age on ultimate outcome may well reflect our attempts to perform these procedures during a very narrow window of 9 to 11 weeks' gestational age when possible.

The role of ultrasonography and amniocentesis in the evaluation of pregnancies at risk for neural tube defects

William A. Hogge, MD, Siva Thiagarajah, MD, James E. Ferguson II, MD, Patricia T. Schnatterly, MS, and Guy M. Harbert, Jr., MD
Charlottesville, Virginia

To assess the relative efficacy of amniocentesis versus targeted (detailed) ultrasonography, 225 patients referred because of an elevated maternal serum α-fetoprotein level (79.6%) or a family history of neural tube defect (20.4%) were evaluated. Ultrasonographic examination alone detected all 26 fetal abnormalities (11 cases of anencephaly, 10 cases of open spina bifida, and five other anomalies). Twenty-eight patients declined amniocentesis; all had normal pregnancy outcomes. Of the 167 patients with apparently normal fetal anatomy by sonography, seven had elevated α-fetoprotein levels but no acetylcholinesterase in the amniotic fluid. Six of these pregnancies resulted in normal infants; one infant had congenital nephrosis. The remaining 160 patients had normal sonograms with normal amniotic fluid α-fetoprotein levels and no fetal malformations at delivery. Although these results suggest that targeted ultrasonography by experienced personnel is a reasonable alternative to amniocentesis in evaluations for neural tube defects, the availability, cost-effectiveness, and diagnostic accuracy of this approach must be well documented in large prospective studies. (Am J Obstet Gynecol 1989;161:520-4.)

Key words: Amniocentesis, ultrasonography, maternal serum α-fetoprotein, neural tube defects

Amniocentesis traditionally has been the procedure of choice for the evaluation of a pregnancy identified as being at risk for a fetus with a neural tube defect. These pregnancies usually were ascertained either because of an elevated maternal serum α-fetoprotein level or because of a family history of neural tube defects. The published management protocols recommend that a level I (basic) ultrasonographic evaluation be performed after two unexplained elevations of maternal serum α-fetoprotein.[1-3] If no explanation is found for the elevated level, an amniocentesis is performed. Between 5% and 10% of the population undergoing amniocentesis would be expected to have an elevated amniotic fluid α-fetoprotein level.[3] In this evaluation protocol, patients then would undergo a detailed (targeted) ultrasonographic examination to delineate the precise lesions, e.g., a neural tube defect, ventral wall defect, or other fetal anomaly.

With the advent of high-resolution ultrasonography, however, modifications to this protocol have been suggested, and the necessity of amniocentesis in all cases has been questioned.[4] In this study we have analyzed the experience in out prenatal diagnosis program and assessed the relative efficacy of amniocentesis versus targeted ultrasonography in pregnancies at risk for a fetus with a neural tube defect.

Material and methods

From September 1985 through August 1988, 225 of the patients evaluated by the prenatal diagnosis program at the University of Virginia were referred because of an increased risk for a neural tube defect (79.6% because of an elevated maternal serum α-fetoprotein level and 20.4% because of a family history of neural tube defect). Patients were initially evaluated between 15 and 21 weeks' gestational age with a mean age of 17.9 weeks at the time of diagnosis. The criteria for referral were an initial maternal serum α-fetoprotein level >3.0 multiples of the median. If the initial value was 2.5 to 3.0 multiples of the median, the test was repeated, and evaluation undertaken if the second result was ≥2.5 multiples of the medians. Before referral the majority of patients had undergone a basic sonogram to exclude incorrect gestational age, multiple gestation, and fetal death. Each patient was counseled regarding the risk of an abnormality and the benefits and limitations of diagnostic ultrasonographic examination and amniocentesis in providing a diagnosis. A targeted ultrasonographic examination then was performed by physicians specifically trained in obstetric ultrasonography. The equipment used was a

General Electric RT3600 with either a 3.5 or 5.0 MHz linear array transducer. Amniocentesis for karyotype analysis and amniotic fluid α-fetoprotein determination thereafter was performed in all cases unless the patient declined further testing. Acetylcholinesterase was assayed on all fluid samples with an amniotic fluid α-fetoprotein level of ≥2.0 multiples of the median. All patients who declined amniocentesis were requested to return for a follow-up ultrasonographic examination four weeks later.

Data on pregnancy outcome were obtained through the ongoing surveillance program of the Prenatal Diagnosis Center. This information was determined by written questionnaires and telephone contact with referring physicians.

Results

Fetal malformations were detected in 26 cases (11.6% of patients evaluated) by the initial targeted ultrasonographic examination (Table I). The mean level of maternal serum α-fetoprotein was 9.0 multiples of the median with a range of 2.9 to 29.0 multiples of the median. Twenty-one of these malformations were neural tube defects (11 cases of anencephaly, 10 cases of myelomeningocele). Of the remaining five cases, four involved a fetus with omphalocele as one component of a multiple malformation syndrome. The fifth patient, referred for evaluation of an elevated maternal serum α-fetoprotein level (2.9 multiples of the median), had a fetus with a Dandy-Walker malformation of the posterior fossa, but there was no obvious defect to explain the laboratory finding. Amniotic fluid α-fetoprotein was 0.8 multiples of the median.

Abnormal ultrasonographic findings were present in three additional cases. These patients had oligohydramnios without identifiable fetal malformations. One spontaneously aborted a grossly normal fetus at 20 weeks' gestation, 2 weeks after the evaluation. Amniocentesis was not performed. The second patient was initially evaluated at 20 weeks' gestation and electively terminated her pregnancy when a follow-up sonogram 4 weeks later indicated persistent oligohydramnios. The third patient was first seen at 18 weeks' gestation and elected to continue the pregnancy. Serial ultrasonographic scans at 2- to 3-week intervals were performed with fetal microcephaly first noted at 27 weeks' gestational age with development of ventriculomegaly at 29 weeks. After delivery at term, clinical evaluation of the infant was suggestive of fetal infection. However, serologic studies and cultures were negative for toxoplasma, cytomegalovirus, rubella, herpes, syphilis, and enterovirus. These latter two patients both had amniocentesis with elevated amniotic fluid α-fetoprotein levels (3.8 and 8.9 multiples of the median, respectively). Electrophoresis for the presence of acetylcholinesterase was inconclusive in both fluid samples (a faint band in patient 3 and a "smear" pattern between the pseudocholinesterase and the acetylcholinesterase position in patient 2).

Table I. Abnormalities detected by ultrasonography

Diagnosis	*No. of cases*	*Maternal serum α-fetoprotein (multiples of median) (mean)*	*Gestational age (wk) (mean)*
Anencephaly	11	13.1	17.6
Open spina bifida	10	4.7	18.6
Omphalocele (with other abnormalities)	4	14.3	16.5
Dandy-Walker malformation	1	2.9	20

There were 28 patients who declined amniocentesis after targeted sonography demonstrated apparently normal fetal anatomy; all had normal pregnancy outcomes. One patient with a maternal serum α-fetoprotein level of 3.2 multiples of the median refused all testing except a basic sonogram for dates performed outside the prenatal diagnosis program. She subsequently was delivered of an infant with a 2 × 2 cm occipital encephalocele.

Of the 167 patients with normal fetal anatomy and amniotic fluid volume by sonography who underwent amniocentesis, seven had elevated amniotic fluid α-fetoprotein levels. Acetylcholinesterase was absent in all cases. Six of these pregnancies resulted in normal infants. The seventh infant had a presumptive diagnosis of congenital nephrosis on the basis of a maternal serum α-fetoprotein value of 19 multiples of the median with an amniotic fluid α-fetoprotein of 43 multiples of the median. This diagnosis was confirmed at birth. The remaining 160 patients had normal amniotic fluid α-fetoprotein levels and no fetal malformations at delivery. There were no spontaneous abortions in the patients who underwent amniocentesis.

Comment

The results of this study indicate that detailed ultrasonography is a reasonable alternative to amniocentesis in the evaluation of pregnancies at risk for a neural tube defect. All defects in our series were detected with ultrasonography before amniocentesis. The 28 patients who declined amniocentesis after a normal ultrasonographic examination were delivered of normal infants. In the remaining patients, except for the case of congenital nephrosis, amniocentesis did not provide any additional information to influence their management. In fact, reliance on the ultrasonographic findings

avoided intervention in the six pregnancies with elevated amniotic fluid α-fetoprotein levels and normal outcome.

The previous recommendations for evaluating gravid women thought to have a fetus at risk for a neural tube defect were based on an efficacy rate of 80% for the ultrasonographic diagnosis of spina bifida.[4, 5] However, during the last decade, advances in ultrasonographic technology and increased experience in the field of obstetric ultrasonography have combined to greatly improve the diagnostic accuracy for detection of fetal abnormalities. The early diagnosis of spina bifida has been enhanced by Nicolaides et al.,[6] who first drew attention to cranial abnormalities that are associated findings in these cases. These signs consisting of alteration in cranial contour ("lemon sign") and abnormalities of the cerebellum and posterior fossa facilitate the diagnosis of spina bifida between 16 and 24 weeks' gestation. Although no large study has yet documented how often a spinal defect will be missed when such signs are used in conjunction with the evaluation of the bony spine, the diagnostic accuracy should be higher than the previously reported 80%. Furthermore, there are defects other than neural tube defect that can cause maternal serum α-fetoprotein levels to be elevated, and discussions of risk on the basis of ultrasonographic diagnosis must include these defects as well.

However, there are a number a limitations to using sonography alone in the evaluation of these cases. The patients in this study were preselected to have a high prevalence of the disorder and were evaluated by examiners experienced at detecting fetal abnormalities. To achieve the necessary diagnostic sensitivity, experienced personnel and high-quality equipment are required. These features are frequently available only in centers with prenatal diagnosis programs. The diagnostic accuracy achieved in this study will not be expected with screening ultrasonographic examinations. Furthermore, even established programs have missed as many as 25% of fetal abnormalities on an initial ultrasonographic examination.[9] No defects were missed by ultrasonography in this study, but our numbers may be considered to be relatively small. Amniotic fluid analysis also provided reassurance in the few cases where ultrasonographic visualization was not fully conclusive. It is therefore imperative that, if fetal detail is not visualized unequivocally, amniocentesis be performed.

The risk of pregnancy loss attributed to amniocentesis is approximately 0.5%. Therefore any comparison of the diagnostic methods must weigh the incidence of procedure-related loss against the missed diagnosis rate. The increased loss rate is a significant consideration in view of the already high rate of fetal death before 20 weeks' gestation in patients with elevated maternal serum α-fetoprotein levels.[7, 8] Ultrasonography as the sole diagnostic modality offers the advantage of safety relative to amniocentesis.

This study confirms that ultrasonography is a very sensitive tool for detecting neural tube defects in a high-risk population. The data from this study, together with those of Drugan et al.[9] and Richards et al.,[4] indicate that the diagnosis would have been missed six times in 880 patients if ultrasonography were the only diagnostic tool. This failure rate of 0.7% is similar to the procedure-related risk of amniocentesis. Thus the preliminary information indicates that targeted ultrasonography alone may be a reasonable alternative when experienced personnel and high-quality equipment are available. However, until more data are available, we believe that the best approach in these patients is a targeted ultrasonographic examination followed by amniocentesis.

We wish to thank Pat Allinson, Joan Hogge, Lisa Kirson, and Mary Ann Shires who provided genetic counseling for the patients in this study, and Nancy Breeden for expert ultrasonographic technical support.

Anomalies not detected before delivery		7/61 (11.5%)

Discussion

Dr. Lewis H. Nelson, Winston-Salem, North Carolina. At the Wake Forest Medical Center patients undergoing diagnostic amniocentesis, either early or routinely, are advised that the pregnancy loss rate from the procedure is 1/300. Risks to the pregnancy from diagnostic ultrasonography, independent of operator judgment, appear to be zero according to safety statements by the American Institute of Ultrasound in Medicine. Patients with an elevated maternal serum α-fetoprotein level above appropriate cutoffs have risks of open neural tube defects or other abnormalities that exceed the risk of an amniocentesis. The authors have presented their experience with the accuracy of ultrasonography, comparing a low-risk procedure with one of essentially no risk if one ignores the skill of the ultrasonographer. The issue of skill or operator effect is one of the two issues one must address in reviewing this presentation.

The authors have alluded to the other issue of small numbers in their study. If one assumes that amniocentesis has a sensitivity rate of 99.5% for the detection of open neural tube defects, then for a comparable sensitivity with 95% confidence limits the authors would have to study approximately 604 cases. In the current study with 26 abnormal cases, the 95% confidence levels give a sensitivity with a lower level of 89.1%, this is not as good as that for amniocentesis. We also must acknowledge that in studying the 604 cases there theoretically would have been two pregnancy losses. It is probably less hazardous legally, assuming good counseling before the procedure, to lose those two pregnancies than to miss the neural tube defect on ultrasonographic examination.

Ultrasonography is an extremely operator-dependent diagnostic procedure. Personnel working as technologists require different training than similar people working as radiology technicians. Although the American Board of Obstetrics and Gynecology has insisted that residents be trained in ultrasonography, each program provides a variable experience. Ultrasonographic training is also part of the fellowship in maternal-fetal medicine. Experience and skill, although less than in residencies, also are variable in those fellowships. The skill level of the authors is not stated in the article and the reader should not assume that it is equal among them. If one ignores the issue of skill, we see an experience as illustrated in Tables I and II. Not all patients were seen at Wake Forest Medical Center.

The authors also do not comment on the quality of the ultrasonographic examination. Are they willing to state that ". . . targeted ultrasonography alone is a reasonable evaluation alternative to amniocentesis . . ." in a patient of reasonable size whose fetus is in a back posterior position? The concluding sentence of the article is more realistic in the world of variable training and academic center egos. The authors state, "Although the preliminary information indicates that targeted ultrasonography may be a reasonable alternative, until more data are available, we believe that the best approach in these patients is a targeted ultrasonographic examination by experienced personnel, followed by amniocentesis." My fear is that the majority of readers will not be responsible to that statement and I strongly encourage the authors to emphasize the point more strongly in their article. It would be advantageous to have an alternative to amniocentesis, but we are far from offering ultrasonography as the alternative at this time.

Dr. Ronald Wade, Charlotte, North Carolina. Are any outcome data available for those with elevated serum α-fetoprotein levels and normal amniotic fluid α-fetoprotein levels? These patients are still at high risk and, even though they may have nonanomalous fetuses, those of us in high-risk obstetrics realize that we need to follow up these patients very closely.

Dr. Hogge (Closing). Dr. Wade, in response to your question, we did not look at that particular information in this study, but we certainly know from just anecdotal experience that there is, in fact, a much higher risk of pregnancy loss, early delivery, and small-for-gestational-age infants in patients with elevated serum levels of α-fetoprotein. There are a number of unusual things that will be coming out of the University of Virginia's prenatal diagnosis program in the form of case reports that have been related to high maternal seurm α-fetoprotein levels in the presence of normal amniotic fluid α-fetoprotein.

I would like to thank Dr. Nelson for his discussion because he said the kinds of things that I would have liked to say very strongly in our Comment section. I will revise it with his comments in mind. We wanted to prove that amniocentesis was, in fact, the best modality. Our data, as you see, led us to have to reassess that particular approach. Hopefully, with large numbers, we will have the information that is unavailable at the

Table I. Patients with normal sonograms selecting amniocentesis

Sept. 1, 1985–Aug. 31, 1989	167/196 (85.2%)
Sept. 1, 1988–Jan. 18, 1989	24/35 (68.6%)

present time. I emphasize what Dr. Nelson said; that is, these patients were somewhat unique in that each was seen by the same group of individuals each time. The ultrasonographers gained increasing experience as the study went on. I don't think this is possible in most places around the country, but our program is small. There is one disconcerting thing, as shown in Table I. The results of the study were discussed with our staff when the study was completed. During the time of the study, about 85% of the women chose amniocentesis after their counseling session. Although the numbers are obviously quite small, you can see that the number has dropped rather dramatically to 68.6% since the study was completed. I would encourage other programs not to have this kind of change in their counseling programs. We will have another session with our staff on our return because this is not what we think should be happening at the present time.

The effects of vibroacoustic stimulation on baseline heart rate, breathing activity, and body movements of normal term fetuses

Lawrence D. Devoe, MD, Nancy A. Searle, BA, David A. Ruedrich, MD, Ramon A. Castillo, MD, and William P. Metheny, PhD

Augusta, Georgia

To determine the fetal biophysical effects of vibroacoustic stimulation produced by an electronic artificial larynx we studied 20 normal term pregnancies assigned either to control (no stimulus) or experimental (stimulus) groups. Each fetus was observed for 3 hours; either no stimulus or a 3-second stimulus was delivered after the first hour. Fetal heart rate baseline and variation, breathing movement incidence, rate, and variation, and body movement incidence data were acquired concurrently and analyzed at 15-minute intervals. Intergroup comparisons showed that, after stimulation, fetal heart rate baseline and variation increased significantly, whereas breathing incidence fell during the first 15 minutes. Within-group analyses showed that poststimulus elevation of fetal heart rate baseline was the only significant time interaction over the 3 hours. Vibroacoustic stimulation appears to be primarily associated with transient alterations in fetal heart rate baseline; concomitant changes in breathing activity probably reflect normal biologic cycles. (Am J Obstet Gynecol 1989;161:524-9.)

Key words: Fetus, fetal heart rate, fetal breathing, fetal movement, acoustic stimulation

Clinical interest in vibroacoustic stimulation of the human fetus is derived from early observations[1, 2] that showed normal third-trimester fetuses had predictable tachycardic responses when brief sound or vibratory stimuli were transmitted through the material abdominal wall. More recently, artificial electronic larynges have been used in antepartum tests to stimulate fetal heart rate (FHR) "reactivity,"[3, 4] and during intrapartum monitoring to predict fetal acid-base status.[5, 6] Investigations of the possible effects of vibroacoustic stimulation on fetal activity have shown (1) gestational age–related differences in FHR, fetal breathing movement, and body movement responses and (2) possible prolongation of these effects at term for ≥1 hour.[7] Because most antepartum fetal evaluations are performed at or near term, it would be important to examine the consequences of vibroacoustic stimulation in this gestational age group with regard to the occurrence, magnitude, and duration of any observed alterations in these activity responses.

The present study was conducted to determine the

effects of a uniform vibroacoustic stimulus produced by an electronic artificial larynx and observed under standardized environmental conditions on baseline FHR, FHR variation, fetal breathing movement and fetal body movement, and fetal breathing movement rate and variability.

Material and methods

Study population. A total of 20 healthy women with pregnancies between 37 weeks' and 40 weeks' gestation were recruited from the general obstetric population at the Medical College of Georgia Hospital and Clinics. All patients had normal prenatal courses with gestational age confirmed by ultrasonographic measurements before week 20 of pregnancy and normal responses to glucose screening between 24 weeks' and 32 weeks' gestation. None of the patients smoked or received medications other than prenatal vitamins. All fetuses were singleton, appropriate in size for dates, and anatomically normal. Patients were entered into the study after they signed an informed consent form approved by the institutional Human Assurance Committee.

Study design. Patients were instructed to eat an approximately 400 kcal breakfast on the day of study, to refrain from eating after study began, and to avoid for the preceding 24 hours drugs with central nervous system effects or beverages that contained caffeine. Before each study, patients were assigned by random lot to either the control (unstimulated) or the experimental (stimulated) group. The principal investigator was not aware of each patient's group assignment during the study.

Studies were conducted in a quiet room with the patient in a semirecumbent position, at 2 hours after a meal. A 1-hour baseline observation period was then begun, after which the principal investigator left the study area and was unable to hear whether the stimulus was applied. An artificial electronic larynx (Western Electric Model 5C, Wallingford, Conn., courtesy of John Kasper, Corometrics Medical Systems) was placed on the maternal abdomen over the fetal vertex and, according to group assignment, either no signal was delivered or a 3-second vibroacoustic pulse was generated. The physical properties of this device have been previously described.[8] The investigator returned to the study room and observation continued for 2 additional hours.

Data collection and analysis. Concurrent observations were made of FHR baseline, acquired from an electronic fetal monitor (Hewlett Packard Model 8040A, Boblingen, West Germany) in the Doppler mode, and hardwired to the serial port of a specially programmed IBM XT microcomputer (512K random-access memory), and of real-time ultrasonographic detection of fetal breathing movement and fetal body movement with a remote-event marker, hardwired to the computer as previously described.[9] The recognition of fetal breathing movements and fetal body movements followed the criteria reported by Patrick et al.[10]

Table I. Outcome of study group patients

	Control group (No stimulus) No. = 10	*Experimental group (Stimulus) No. = 10*
Gestational age at study (wk)	38.7 ± 0.9	37.9 ± 0.3
Gestational age at delivery (wk)	40.0 ± 0.7	40.0 ± 1.3
Birth weight (gm)	3255 ± 384	3412 ± 179
5-Minute Apgar score	8.8 ± 1.1	8.8 ± 0.7

Each value expressed as mean ± SD.

At the conclusion of each study the following biophysical observations were analyzed off-line at 15-minute intervals: (1) baseline FHR; (2) long-term FHR variation (1-minute coefficient of variation of FHR baseline); (3) percentage of time spent breathing; (4) breath rate; (5) coefficient of variation of mean breath interval; and (6) percentage of time spent in body movements.

Statistical treatment of the data used a correlational analysis of variance. A p value <0.05 was considered significant.

Results

All results are presented as mean ± SD.

Obstetric outcomes. All patients were delivered of infants at term and their infants had no intrapartum or postpartum complications. Each neonate was judged to be of appropriate size for gestational age, and had a 5-minute Apgar score >7. All neonatal courses were normal. A comparison of gestational age at testing and delivery, birth weight, and mean 5-minute Apgar scores between control and experimental groups is shown in Table I. There were no significant differences between the groups for any of these variables.

FHR baseline. Mean 15-minute FHR baseline values of the control and experimental groups were 135 ± 6 beats/min and 136 ± 8 beats/min, respectively, and were not significantly different during the initial 60 minutes of observation (Fig. 1). The FHR baseline of the experimental group increased significantly (to 147 ± 9 beats/min) during the first 15 minutes after stimulation when compared with the control group ($p < 0.05$). Analysis of variance with repeated measures confirmed that the significant change in mean baseline FHR for the experimental group was confined to the first 15 minutes after stimulation ($p = 0.001$). Initial 60-minute control period values of mean 1-minute coefficients of variation of FHR baseline were similar in the experimental and control groups (0.045 ± 0.02

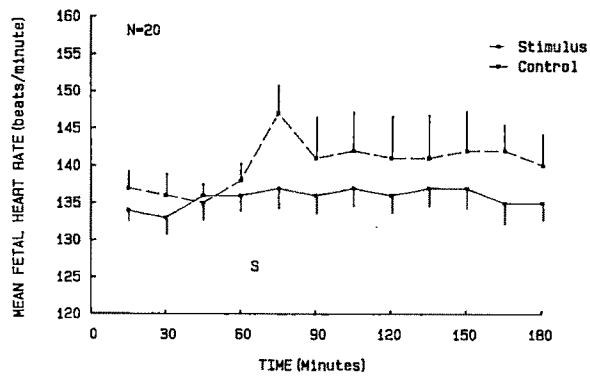

Fig. 1. Mean baseline FHR is plotted in 15-minute intervals before and after vibroacoustic stimulation(s). Experimental group is indicated by *broken line;* control group is indicated by *solid line. Bars* represent SEM.

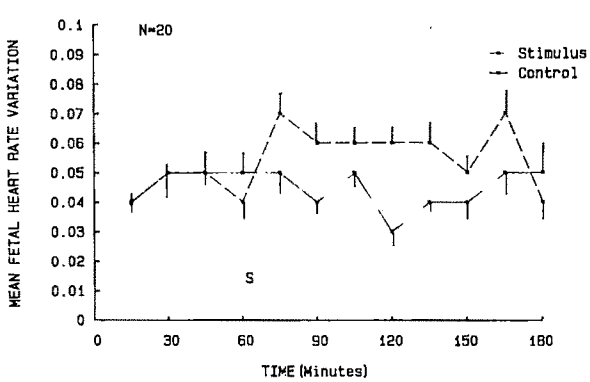

Fig. 2. Mean 1-minute coefficient of variation of baseline FHR is plotted in 15-minute intervals before and after vibroacoustic stimulation(s). Experimental group is indicated by *broken line;* control group is indicated by *solid line. Bars* represent SEM.

and 0.048 ± 0.03, respectively) (Fig. 2). Mean 1-minute coefficient of variation of baseline FHR also increased for the experimental group during the first 15 minutes after stimulation, when compared with the control group ($p < 0.05$). Analysis of variance with repeated measures showed no significant differences in either group for the remainder of the study period.

Fetal breathing activity. The mean 15-minute percentage of time spent breathing was similar for both groups (control group: 37.4% ± 27.8%; experimental group: 29.0% ± 25.3%) during the first hour of study. After stimulation there was a significant fall in breathing activity for the experimental group to 17.8% ± 15.9% ($p < 0.05$) when compared with the control group (Fig. 3). Analysis of variance with repeated measures showed that trends in breathing activity were not significantly different in either the experimental or control group. Fetal breath rates were similar in both groups during the control period and after stimulation

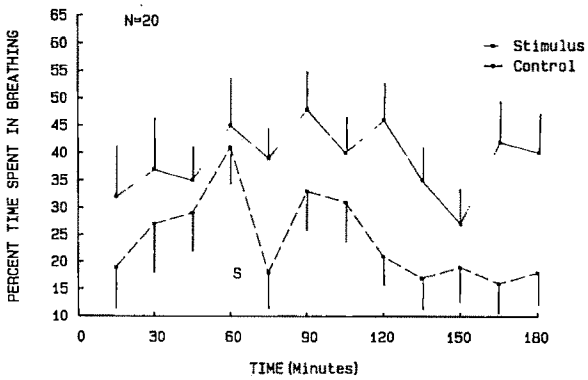

Fig. 3. Mean time spent breathing is plotted in 15-minute intervals before and after vibroacoustic stimulation(s). Experimental group is indicated by *broken line;* control group is indicated by *solid line. Bars* represent SEM.

(Fig. 4) as were mean 15-minute coefficients of variation of breath intervals (Fig. 5).

Fetal body movements. The mean 15-minute percentage of time spent in movement was 4.4% ± 6.0% and 4.9% ± 5.0% in the experimental control groups, respectively, during the control period. These values were not significantly different. After stimulation there were no immediate changes in this activity. Although a peak in fetal body movement incidence occurred at 120 minutes in the experimental group, analysis of variance failed to show significant effects with time in either group over the total study period (Fig. 6).

Individual fetal responses. Eight of the experimental group fetuses had an increase in mean baseline FHR (>10 beats/min) and six had a decline in fetal breathing movement during the first 15 minutes after stimulation (>50%). Two fetuses had no apparent biophysical response to the stimulus. When behavioral state vectors (e.g., FHR variation, fetal movement incidence, and fetal breathing patterns) were taken into consideration, there were no apparent differences in prestimulus states between fetuses with altered biophysical activities and those with unchanged poststimulation activities. Although rapid eye movements were not continuously recorded as part of the study protocol, the consistent presence of irregular breathing activity, the pattern of baseline FHR variability, and relatively low incidence of fetal body movement, suggested that all of the fetuses in both the control and the experimental group were either entering or already in an active sleep state.

Comment

This study has shown that a uniform brief vibroacoustic stimulus is associated with alterations in selected biophysical parameters of normal term human fetuses. Under standardized observation conditions with the use of a computerized data acquisition and analysis system, we have been able to describe precisely the mag-

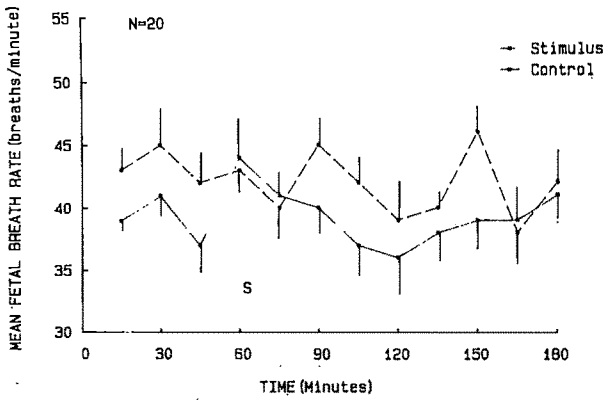

Fig. 4. Mean fetal breath rate is plotted in 15-minute intervals before and after vibroacoustic stimulation(s). Experimental group is indicated by *broken line;* control group is indicated by *solid line. Bars* represent SEM.

nitude and duration of these responses. Most healthy term fetuses appear to respond to an external vibroacoustic signal with transient increases in baseline FHR and FHR variation, largely confined to the first 15 minutes after stimulation. Concurrently, fetal breathing activity declines sharply in the stimulated group during the first 15 minutes and throughout the remainder of observation in both groups. This probably reflects naturally occurring biologic cycles[11] rather than sustained poststimulus effects. Poststimulus changes in biophysical activity appear to be selective as fetal body movement incidence and breath interval variability were not significantly changed. The presence or absence of fetal "responses" to vibroacoustic stimulation are not entirely predictable, as two fetuses did not show changes in biophysical activity. An important observation is that any alteration in biophysical response that might be attributed to vibroacoustic stimulation does not seem to be prolonged for more than 15 minutes after stimulation.

Whereas vibroacoustic stimulation of the human fetus has been studied >50 years,[1] the recent reports of Gagnon et al.[7,8] were among the first to explore possible mechanisms of its action. The present study is similar in design and intent to those of Gagnon et al. but differs in several important respects. First, the observation period was 60 minutes longer so that at least one completed biologic cycle[11] would be included during the study. The actual pulse duration was 2 seconds shorter. The statistical treatment of our study data differed from theirs in that our analysis focused on the intragroup effects of time and the possible intergroup differences that might be attributed to the experimental maneuver. These differences in study approach suggest that between groups, the most likely sources of differences in any biophysical parameter value, excluding the initial 15-minute poststimulation period, result from normal biologic cycles, as described by Campbell et al.[11]

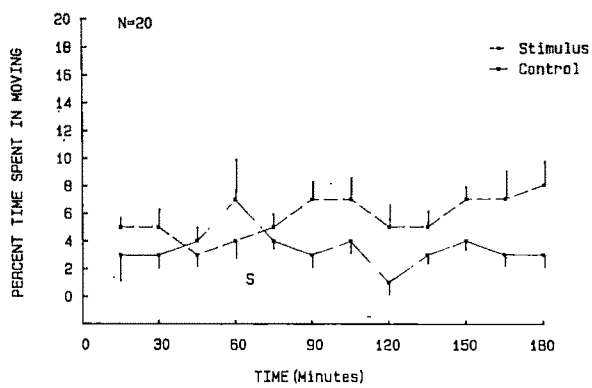

Fig. 6. Mean percentage of time spent in movement is plotted in 15-minute intervals before and after vibroacoustic stimulation(s). Experimental group is indicated by *broken line;* control groups is indicated by *solid line. Bars* represent SEM.

The mechanism of action by which vibroacoustic stimulation appears to affect the fetus is undetermined. Grimwade et al.[12] have suggested that the vibratory component is more important than the acoustic component in eliciting responses. Fetal sensitivity to this stimulus may be related to the maturation of sensory pathways that involve Meissner corpuscles, as the occurrence and magnitude of a poststimulus response are directly related to length of gestation.[7] Our data demonstrate that, even at term, not all normal fetuses respond to vibroacoustic stimulation and thus suggest that the stimulus-response characteristics of this system may continue to vary throughout pregnancy.

Our data do not support the speculation that vibroacoustic stimulation alters subsequent fetal behavioral states,[7] as characterized by coherent patterns of motor activity that persist for at least several minutes.[13] If significant or prolonged alterations in state had occurred, significant coincident differences in FHR variation, body movement incidence, breathing activity,

and FHR baseline would have been apparent, especially because the study population was at a gestational age when behavioral stages are well organized. It appears more likely that poststimulus changes involve individual state vectors for brief periods of time.

In conclusion, we have attempted to identify and clarify some of the fetal biophysical effects associated with vibroacoustic stimulation, delivered by an electronic larynx. These effects are brief and do not generally persist more than 15 minutes after the stimulus is applied. The directions in which state-related activities are changed and the lack of uniformity in poststimulus fetal responses suggest that disorganization of behavioral state may occur after vibroacoustic stimulus. It is important to obtain additional information concerning the mechanisms of vibraocoustic stimulation before it can be recommended without qualifications for assessment of fetal well-being.

Discussion

DR. GUY M. HARBERT, JR., Charlottesville, Virginia. For >50 years it has been known that the fetus responds to sound and vibration. In 1977 clinical application of these observations was stimulated by Read and Miller[1] when they published preliminary results that indicated acoustic stimulation of the fetus evoked accelerations in FHR that correlated well with fetal outcome. They proposed that a positive fetal response to auditory stimulation would obviate the need for an oxytocin challenge test. In 1984 Serafini and colleagues[2] at the University of Maryland reported that acoustic stimulation was a safe and rapid test of fetoplacental sufficiency comparable to nonstress tests in reliability. Over the next 2 years, retrospective studies championed the advantages of fetal acoustic stimulation in the decrease in the incidence of nonreactive nonstress tests and in the reduction of testing time.

With the use of the number of published manuscripts as a guide, it would appear that fetal acoustic stimulation came of age in the latter half of 1987.

In 1988 there were articles that suggested ultrasonic imaging of fetal facial reactions and response decrement patterns to acoustic stimulation may be a useful tool for in utero neurologic evaluation[3] and that differences in response may distinguish the small-for-gestational-age fetus from one with appropriate growth.[4] Investigators who performed Doppler flow velocity measurements demonstrated a significant decrease in umbilical peak-systolic/end-diastolic ratios immediately after acoustic stimulation.[5] Others have recorded the sound pressure in amniotic fluid created by application of an electronic artificial larynx to the abdominal surface of pregnant ewes.[6]

Wheras fetal acoustic stimulation is generally considered to be safe, severe fetal bradycardia caused by external vibratory acoustic stimulation has been reported.[7] With an increase in interest in and application of acoustic stimulation of the fetus, this presentation, which describes the occurrence, magnitude, and duration of some aspects of the fetal response to a vibroacoustic stimulus, is very appropriate.

The investigational protocol is well designed, the control and experimental groups are well matched and the conclusions are appropriate for the data presented. Extension of the observation period to include at least one completed biologic cycle is a significant contribution to better understanding of the fetal biophysical effects. A weakness of the experimental design is that a cross-over study was not performed. This would have doubled the data points without jeopardizing the initial randomization. Because each subject would then serve as her own control, it would have emphasized the differences or lack thereof that occurred as a result of vibroacoustic stimulation. However, failure to do this cross-over does not detract from the significance of the findings.

The statistics used are appropriate but are sometimes confusing in their presentation. For example, it is stated that fetal breathing activity in the experimental group was decreased significantly after stimulation, yet the

analysis of variance with repeated measures showed that this trend was not significantly different from that observed in the control group. The latter statement could lead one to question whether there was really a change in fetal breathing activity in response to the stimulus.

I have three other questions. First, under individual fetal responses, it is reported that eight of the experimental fetuses had an increase in mean baseline heart rate and six had a decline in fetal breathing movements. This leaves the possibility that two of the fetuses that were stimulated showed no response in either heart rate or breathing movements. Is this correct?

Second, you state that the consistent presence of irregular breathing activity, the pattern of baseline FHR variability, and the relatively low instance of fetal body movement suggests that all of the fetuses who received stimulation were either entering or already in an active sleep state. Would not this statement also apply to the control group?

And third, other investigators have reported a significant negative correlation between the maximum of the first FHR acceleration and the prestimulation basal FHR.[8] Did you note such a correlation?

I compliment Dr. Devoe and colleagues on their study of the fetal biophysical effects associated with vibroacoustic stimulation and encourage them to continue and expand their investigations. All too often in obstetrics we have seen new techniques accepted as dogma in clinical situations with only minimal understanding of the mechanisms involved. With the apparent proliferation of interest in fetal vibratory acoustic stimulation each contribution of basic information such as presented here will enable us to better interpret and understand the safety and the significance of stimulus response in clinical situations.

DR. WILLIAM F. O'BRIEN, Tampa, Florida. This is excellent and important work for a very important reason. We are getting farther along in the avoidance of contraction stress tests by doing vibroacoustic stimulation in the patient who has nonreactive nonstress test results. However, we begin to lose track of the fact that what we really are trying to do is to find that very small group of fetuses that have a high likelihood of poor outcome. Reactivity after vibroacoustic stimulation offers a degree of reassurance similar to reactivity without vibroacoustic stimulation. It is important for us to know what vibroacoustic stimulation does to other test parameters such as the biophysical profile. How long after a vibroacoustic stimulation test must we wait before performance of a biophysical profile? Dr. Devoe's study suggests to me that a biophysical profile done 30 to 45 minutes later is not affected by a preceding vibroacoustic stimulation. I want to ask Dr. Devoe whether he agrees with this conclusion.

DR. JOHN W. C. JOHNSON, Gainesville, Florida. I also congratulate Dr. Devoe on a very well-designed study and particularly on his precautionary conclusions. There are a number of people who have raised concerns about the acoustic pressure generated by this test and to date there really have not been any careful follow-up studies as to whether there might be auditory damage as a result of this study. I wonder whether Dr. Devoe has any information or concerns about this issue.

DR. DEVOE (Closing). I appreciate the constructive insights of Dr. Harbert and agree that a cross-over study would have been ideal if it would have been practical to have arranged second sessions for each patient. In response to his first question, the analysis of our data shows that extension of the study period for 2 hours after stimulation supports the conclusion that alterations in breathing activity, which occurred in both groups, are unlikely to have resulted from stimulation. As to the next question, two fetuses in the experimetnal group did not show altered FHR or breathing activity after stimulus. It is also probable that fetuses in both the control group and the experimental group were entering or already in active sleep before stimulation. Our observations with regard to prestimulus baseline and first FHR accelerations are similar to those reported by Gagnon et al.

Dr. O'Brien raises a thoughtful question (i.e., does vibroacoustic stimulation have a lingering effect on subsequent biophysical tests?). Our data suggest that such an effect would be unlikely after the first 15 minutes after stimulation.

Dr. Johnson focuses on an area of common concern: is this technology safe for the infant? Whereas no adverse effects have been reported for our study infants, I cannot offer this as a blanket endorsement as our numbers are small and the follow-up period was confined to the time spent in the normal newborn nursery.

Seminoma in pubertal patient with androgen insensitivity syndrome

W. Glenn Hurt, MD,[a] Joann N. Bodurtha, MD,[b] Janice B. McCall, MD,[c] and M. Moinuddin Ali, MD[d]

Richmond, Virginia

The case of a 14-year-old girl with complete androgen insensitivity syndrome and metastatic seminoma is reported. She was treated by bilateral adnexectomy, removal of paraaortic lymph nodes, postoperative radiation, and estrogen replacement therapy. She represents the fourth case of gonadal malignancy to be reported in a teenage patient with androgen insensitivity syndrome. (AM J OBSTET GYNECOL 1989;161: 530-1.)

Key words: Seminoma, androgen insensitivity syndrome, testicular feminization

Complete androgen insensitivity syndrome is a genetic disorder with X-linked inheritance that is associated with an XY karyotype, bilaterally maldescended testes, and androgen insensitivity caused by androgen receptor defect(s). Individuals with androgen insensitivity syndrome are prone to develop gonadal tumors but have been observed to do so at a later age and with less frequency than those with gonadal dysgenesis. We believe this is the fourth case of invasive gonadal malignancy to be reported in a teenage patient with androgen insensitivity syndrome.

Case report

A 14-year-old nulligravid patient was referred because of an abdominopelvic mass and primary amenorrhea. The patient had a female phenotype, Tanner III breast development, and no secondary sexual hair. The blind vagina was 3 cm long. A large, firm mass filled the pelvic and lower abdominal cavities and extended to within 3 cm of the lower margin of the umbilicus.

The β-subunit of human chorionic gonadotropin, α-fetoprotein, CA 125, and carcinoembryonic antigen levels were normal. Results of chest radiography and excretory urography were normal. Transvaginal fine-needle aspiration of the mass was performed; the cytopathologic diagnosis was dysgerminoma-seminoma.

Exploratory laparotomy revealed a solid left adnexal mass that filled the lower abdominal and pelvic cavities, a right adnexal mass that resembled a testicle, and two suspicious left paraaortic lymph nodes underlying the left renal vessels. There was no evidence of a uterus. Both adnexa, the two lymph nodes, and a portion of the omentum were removed.

The left adnexal mass measured 17 × 12 × 6 cm and weighed 930 gm. Histologically it was typical of a seminoma. The right adnexal mass was an immature testis that contained foci of intratubular seminoma. Metastases of 1 × 2 cm were present in each of the two left paraaortic lymph nodes.

The patient was treated with radiation therapy as for a stage IIA testicular seminoma (M. D. Anderson modification of the Dixon and Moore staging system). A 4 MeV linear accelerator was used to deliver a total dose of 2445 cGy to the pelvic and paraaortic areas with a boost of 600 cGy to the site of the positive paraaortic nodes. Three weeks later, the mediastinum and supraclavicular fossae were treated with a total dose of 2550 cGy. The patient takes conjugated estrogen as replacement therapy. She is now well and free of disease 18 months after surgery.

Cytogenetically, the patient was reported to have a 46,XY karyotype with no evidence of mosaicism. The presence of a structurally normal Y chromosome was confirmed by C-banding. Studies performed on skin from the labia majora revealed 5 α-reductase activity of 18.5 pmol/h/mg protein (normal > 1.0) and an androgen receptor level of 1.1 fmol/mg protein (normal > 15.0). The patient is reported to have had an aunt who was not able to have children because she had "the internal organs of a male."

Comment

In their study of 181 cases of androgen insensitivity syndrome, Morris and Mahesh[1] found a 22% overall incidence of malignant gonadal tumors. The majority of the malignancies were seminomas, but there was also a malignant teratoma and a Sertoli-Leydig cell tumor. Of the patients with gonadal tumors in their series, one was a teenager, two were patients in their 20s, and the remainder were 30 years of age or older. The one teen-

6/6/12994

ager, reported originally by Carmichael and Oldfield,[2] was 14 years old and had a malignant teratoma of the left gonad. This is the youngest patient with androgen insensitivity syndrome reported with an invasive gonadal malignancy.

Perez-Palacios and Jaffe[3] reported that one of their patients with androgen insensitivity syndrome had an 18-year-old sibling who died with an "abdominal malignancy" that was a gonadal stromal tumor and was associated with absence of the uterus. The fact that complete androgen insensitivity syndrome is an X-linked trait suggests that this sibling may have had the disorder.

Horcher et al.[4] reported a 15-year-old patient in whom they diagnosed androgen insensitivity syndrome. On the basis of the recommendation that patients with androgen insensitivity syndrome be allowed to complete pubertal feminization, they chose not to perform prophylactic gonadectomy at the time the diagnosis was made. When the patient was 16, she had surgery because of increasing pain in the left inguinal region. The left testis was partially within the inguinal canal, and this was thought to be the cause of the pain. The right testis was free within the abdomen; it contained a seminoma.

To calculate the potential for the development of gonadal tumors in patients with androgen insensitivity syndrome, Manuel et al.[5] combined a series of 23 cases of patients with no tumors with 82 cases from the medical literature and determined that the expectancy of tumors is 3.6% at age 25 and 33% at age 50. They conclude that "if a risk of something less than four percent is acceptable, delay in removal of the gonads may be entertained until approximately the age of thirty."

More recently Muller and Skakkebaek[6] have described carcinoma in situ in the testes of three of eight consecutive patients with incomplete androgen insensitivity syndrome at 2 months and at 13 and 14 years of age. These findings led them to recommend gonadal biopsy as soon as the syndrome is diagnosed. If the biopsy results reveal carcinoma in situ, they advocate immediate gonadectomy. If the biopsy was performed in early childhood with negative results, they recommend that it be repeated at puberty since the accuracy of a single biopsy is not known to determine whether gonadectomy can be further delayed. The recommendation that patients have serial biopsies and that gonadectomy be based on biopsy results has not gained wide acceptance.

Women with XY karyotypes are at increased risk for development of gonadal malignancies. Those with gonadal dysgenesis are more likely to develop gonadal malignancies and at a younger age than those with androgen insensitivity syndrome. It is accepted that patients with gonadal dysgenesis should have prophylactic gonadectomy as soon as their condition is diagnosed. The fact that three young patients with incomplete androgen insensitivity syndrome have been found to have carcinoma in situ of the testes and that four teenagers have been reported to have invasive gonadal malignancies suggests the need to reevaluate the recommendation that prophylactic gonadectomy in androgen insensitivity syndrome patients be postponed to permit pubertal growth and feminization. Gonadal biopsy may be a method to determine when to perform gonadectomy.

Successful pregnancy after a liver transplant

Cynthia J. Sims, MD, Kathy B. Porter, MD, and Robert A. Knuppel, MD, MPH
Tampa, Florida

The literature contains limited reports on successful pregnancy outcomes after a liver transplant. We report an uncomplicated pregnancy and delivery in a patient 35 months after liver transplantation because of chronic active hepatitis with resultant liver failure secondary to non-A non-B hepatitis. (AM J OBSTET GYNECOL 1989;161:532-3.)

Key words: Liver transplant, pregnancy outcome

This is a case report of a patient with a liver transplant who had a subsequent successful pregnancy outcome. Because only a few cases have been reported with varied outcomes, information gained from these reports during pregnancy and from other transplant recipients will assist in the guidance of obstetric management of these cases.

Case report

On June 11, 1987, a 26-year-old gravida 1, female was seen at an estimated gestational age of 10 weeks. Her medical history was remarkable for non-A non-B hepatitis that led to chronic active hepatitis and subsequent liver failure. In 1984 she underwent an orthotopic liver transplant with a relatively uncomplicated postoperative course. Over the subsequent year she was maintained on the immunosuppressive agent cyclosporine, 150 mg orally every 12 hours. After this regimen, results of liver function tests remained within the normal range without evidence of rejection. No serious infections were noted during the 6 months before pregnancy.

We chose to continue the patient on the immunosuppressive therapy that was established before pregnancy. Initial and subsequent laboratory evaluations of hepatic and renal function were normal. Serial sonograms revealed adequate growth of the fetus. No fetal anomalies were detected by ultrasonographic evaluation. At 32 weeks' gestation weekly nonstress tests were started and were noted to be reactive. At 38 weeks' gestation the fetus was noted to be in a breech presentation. On admission to the labor and delivery suite for an external cephalic version, the fetus spontaneously turned to a vertex presentation. The cervical examination revealed a Bishop score of 9, thus oxytocin induction of labor was begun. The patient underwent a spontaneous vaginal delivery of a 2724 gm female infant 13 hours later. Apgar scores were 9 at 1 and 5 minutes, respectively. The neonate did not have any obvious anomalies. After an uneventful 2-day nursery stay, the neonate was discharged to home with her mother. Breast-feeding was not advised while taking cyclosporine. At 3 months of age, the infant had a lower urinary tract infection that promptly responded to therapy. The mother and her infant were doing well 12 months after delivery.

Comment

The first case report of a successful pregnancy in a patient after a liver transplant was reported by Walcott et al. in 1978.[1] In 1980 Myers et al.[2] reported two different term pregnancies in the same patient. Newton et al.[3] reported the fourth third-trimester pregnancy associated with a liver transplantation patient. The pregnancy was complicated by abruptio placentae and preterm delivery at 27.5 weeks' gestation; both mother and infant survived. In each case the patient was immunosuppressed with azathioprine. In 1988 two cases were reported by Venkataramanan et al.[4] Immunosuppression was achieved with cyclosporine.

Standards of care for liver transplant recipients who conceive are not well established. When managing a liver transplant patient during pregnancy many issues still raise concern. Little is known about the effect of the pregnancy precipitating rejection of the transplanted liver. Also, the transplanted liver may affect the course of the pregnancy. These effects were not observed in our patient.

A particular concern during pregnancy in liver transplant recipients is the potential harmful effect of chronic maternal immunosuppression. The literature available on renal transplant patients served as an important guide in the management of our patient. However, the majority of the literature contains information about the immunosuppressive agent azathioprine. Hu-

man organ transplant recipient survival rate has been improved by use of the immunosuppressive agent cyclosporine. Cyclosporine is lipid soluble, widely distributed in the body, and highly metabolized. Cyclosporine has been detected in cord blood, placenta, amniotic fluid, and breast milk. The toxicity of cyclosporine metabolites is unknown. Cyclosporine did not produce any chromosomal abnormalities in animals exposed to chronic therapy. Further follow-up is necessary to evaluate the possible effects on the fetus exposed to chronic cyclosporine immunosuppression in utero.

The care of the organ transplant recipient during pregnancy requires a team approach. Not only are the immediate concerns of the pregnancy important, but long-term follow-up of the mother and her infant will be relevant to fully evaluate the extent of possible complications.

A clinical-pathologic study of mixed müllerian tumors of the uterus over a 16-year period—The Medical College of Georgia experience

Donald G. Gallup, MD, Donna S. Gable, MD, O. Eduardo Talledo, MD, and Luther B. Otken, Jr., MD

Augusta, Georgia

From 1972 through 1987, 40 patients at the Medical College of Georgia were assessed with a diagnosis of mixed müllerian tumors which constituted 3.5% of all female genital tract malignancies. The mean patient age was 65.3 years; 60% of the patients had stage I disease. Of those patients with clinical stage I disease, more advanced disease was found at celiotomy in 33%. Retroperitoneal nodes were positive for malignancy in 35% of 20 patients who underwent node sampling. Cell washings were positive in 12%, and 9% had omental metastases. Forty-seven percent had homologous tumors; 53% of tumors were heterologous. Relatively poor prognosis was associated with large tumor volume, vascular invasion, nodal metastases, and disease outside the uterus. The overall survival rate was 32%; 14 of 24 patients with stage I disease are dead of disease. Of patients dead of disease, 92.5% had distant metastases. Adjuvant therapy with a combination of VP-16, cisplatin, and irradiation was beneficial in four high-risk patients. (AM J OBSTET GYNECOL 1989;161:533-9.)

Key words: Mixed müllerian tumors, uterus, cancer

Mixed müllerian tumors of the uterus have been traditionally associated with a relatively poor prognosis. Controversies about some prognostic factors continue.

Mixed tumors with homologous patterns (tissue elements entirely indigenous to the uterus) have been thought to be associated with a better survival than mixed tumors with heterologous elements (tissue with cells foreign to the uterus). If the heterologous element present is other than chondrosarcoma (i.e., striated muscle), survival has been relatively poor.[1,2] The mixed müllerian tumors are highly aggressive neoplasms that spread early to regional nodes and adjacent tissues. Nodal involvement is usually associated with deep myometrial invasion. In an earlier report, DiSaia et al.[3]

noted pelvic node metastases in one third of the patients who had operations. The single most important factor signaling poor prognosis at diagnosis is extrauterine extension of disease. Hematogenous spread of both homologous and heterologous tumors is not uncommon.[4-8] Controversy regarding the role of primary surgical staging versus preoperative pelvic irradiation continues. The role of presently available chemotherapy as an adjuvant in primary treatment is also unsettled. This article is a retrospective review of the patients assessed with a diagnosis of mixed müllerian tumor who were managed at one institution during a 16-year period.

Material and methods

The clinical records of all patients assessed with a diagnosis of mixed müllerian tumor of the uterus at the Medical College of Georgia from Jan. 1, 1972, to Dec. 31, 1987, were reviewed. Follow-up information was obtained from tumor records, and when necessary by telephone and correspondence. Histopathologic material was reviewed with two pathologists (D. S. G. and L. B. O.). Re-cuts and special stains were obtained and reviewed when necessary.

The patients were retrospectively staged based on the 1971 International Federal of Gynecology and Obstetrics criteria for adenocarcinoma of the uterine corpus. In addition to the clinical stage, patients who underwent celiotomy were also staged on a surgical-pathologic basis.

Results

During the study, 49 patients were assessed with a diagnosis of mixed müllerian tumor of the uterus. Nine patients were removed from the study group because of inadequate material to make the diagnosis (5 patients), or because of misdiagnosis after the slides were reviewed; thus 40 patients qualified for the study group. These cases constituted approximately 3.5% of all female genital tract malignancies managed at the Medical College of Georgia during the same period.

The mean age was 65.3 years, with a range from 47 to 89 years. Only one patient was <50 years old, and 26.2% were <60. All but three women were postmenopausal. The mean parity was 2.9, but 14.3% of the patients were nulliparous. One third of the patients were white; 67% were black. Thirty-three percent had diabetes mellitus. The most frequent initial primary symptom was abnormal vaginal bleeding, which occurred in 95% of patients. Of the two patients who had no bleeding, one had passage of tissue, and the other, who had prior irradiation treatment, had ascites. Other symptoms noted in addition to bleeding were pain (17%), increased girth (11%), and weight loss (5%). Exogenous estrogen was used from 5 to 25 years by 10% of the patients. Of those with symptoms, 9.5% of patients gave a symptom history of <1 month; 48%, <3 months, and 90%, <6 months. Only 7.5% had a history of prior pelvic irradiation treatment for cervical cancer. Additionally, one patient had prior breast cancer and one had chronic lymphocytic leukemia. Twenty-five percent of the patients weighed >20% of their ideal body weight. Results of cervical cytologic testing, available in 25 patients, were suspicious for malignancy in 44% and inflammatory in 12%.

When International Federal of Gynecology and Obstetrics criteria for staging were applied to the study cases, 60% had clinical stage I disease; 20% had clinical stage II disease; 2.5% had clinical stage III tumors, and 17.5% had clinical stage IV disease. Six women with clinical stage I and II disease did not undergo hysterectomy. Thirty-three percent of women undergoing surgery were restaged from clinical stage I to more advanced disease. Four of five patients with clinical stage II disease had more advanced disease at celiotomy. Retroperitoneal nodes were positive for tumor in 35% of 20 patients who underwent node sampling (Table I). Nine percent of patients undergoing celiotomy with hysterectomy and removal of the ovaries had omental metastases, regardless of whether nodes were sampled. Cul-de-sac washings were positive in 12%. All living patients have been followed up at least 9 months. When survival was correlated with clinical

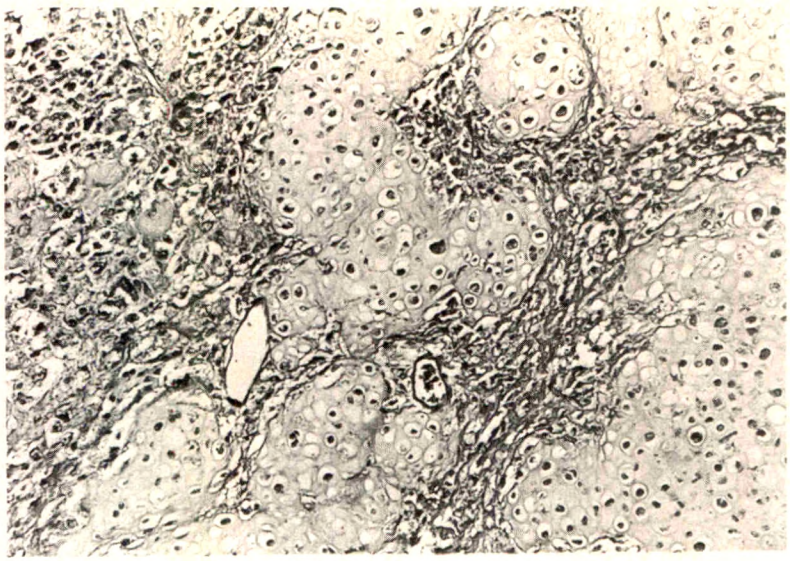

Fig. 1. Chondrosarcoma. Elements of cartilage are noted with a heterologous tumor in a 72-year-old woman who died within 6 months of surgery.

International Federal of Gynecology and Obstetrics stage, 58.3% with stage I were dead of disease (Table II). In one of the patients with stage I who was considered dead of disease, death was treatment-related. She developed pelvic recurrence with an obstructed ureter and was treated with methotrexate, actinomycin D, and cyclophosphamide. After the second chemotherapy course she died of toxicity manifested by thrombocytopenia, leukopenia, and eventual disseminated intravascular coagulation. Three patients with clinical stage I are living with disease at 9, 13, and 29 months. Two patients with clinical stage II disease are living with disease at 12 and 13 months. Of patients dead of disease, 39% died within a 6-month period; 50% died in a period of 7 to 12 months; and 11% died after a period of 13 months. One of these latter three died 36 months after diagnosis. Seventy-four percent of the 27 black patients are dead of disease, compared with 46% of the 13 white patients.

Of 11 patients with clinical stage I or II disease who underwent surgery and were found to have extrauterine spread, 6 are dead and 5 are living and are presumed to have disease. Of the 15 patients with disease confined to the uterus who underwent surgery, 46.7% are dead of disease. If patients with stage III and IV are added to the group with extrauterine spread, there are no survivors without evidence of disease. Nineteen patients (47.5%) had homologous mixed müllerian tumors, and 63% are dead of disease, whereas 67% of the 21 patients with heterologous mixed müllerian tumors are dead of disease. The various elements of the sarcoma (i.e., chondrosarcoma) did not appear to affect survival (Fig. 1). Tumor volume was obtained from pathology reports in 26 patients. Of 18 patients with tumor size ≥5 cm, 55% are dead of disease. Eight patients had tumors <5 cm in size, and only 25% are dead from disease. Tumor volume was not always related to depth of myometrial invasion. Five patients with tumor >5 cm who are dead of disease had only superficial invasion. Vascular invasion was identified in 14 patients; 64.2% are dead of disease, compared with 12 patients without identifiable vascular invasion, only 25% of whom are dead of disease. In patients with vascular invasion, 43% had sarcoma in the vessels and 28% had carcinoma (Fig. 2). The remaining patients had a mixture of the elements in vascular spaces.

The presence of vascular invasion as a poor prognostic factor is illustrated by the case of a 67-year-old woman with a stage IB heterologous mixed müllerian tumor. She had only superficial myometrial invasion of a polypoid lesion that filled the cavity. Paraaortic and pelvic nodes removed contained no tumor. Cell washings were negative, and an omental biopsy revealed no tumor. Because of tumor in vascular spaces, she was offered adjuvant chemotherapy but refused. Four months after surgery, she died of massive liver and lung metastases.

Mitotic activity did not play a significant role in survival. Regardless of outcome, almost all patients had high counts (>10 mitoses per 10 high-power fields in the sarcomatous element. The carcinoma/sarcoma ratio also did not affect survival. The overall mortality in this series was 67.5%.

In patients dying of disease, the location of tumor was assessed by physical examination, x-ray studies, or postmortem examination. Two patients died with local recurrence only, whereas 92.5% had distant metastases, either alone or combined with local recurrence (Fig.

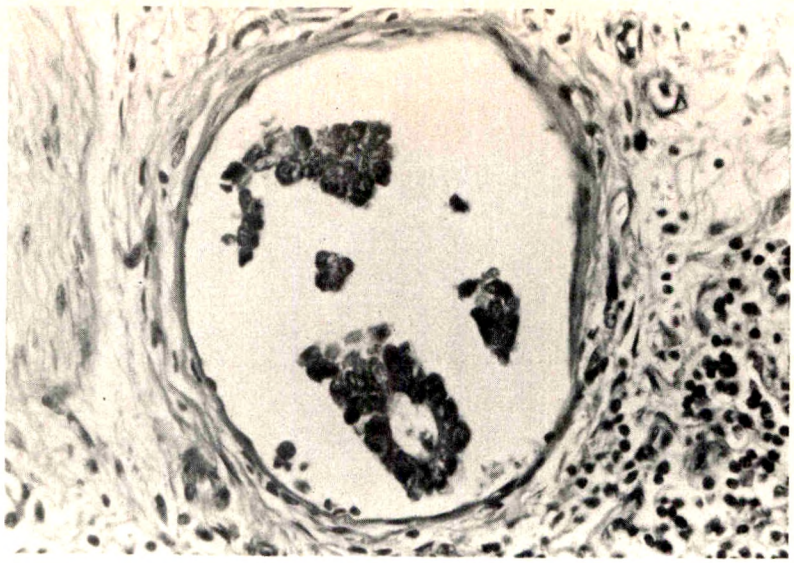

Fig. 2. Metastatic carcinoma in a vascular-lymphatic space in the uterus of a patient who died 9 months after treatment.

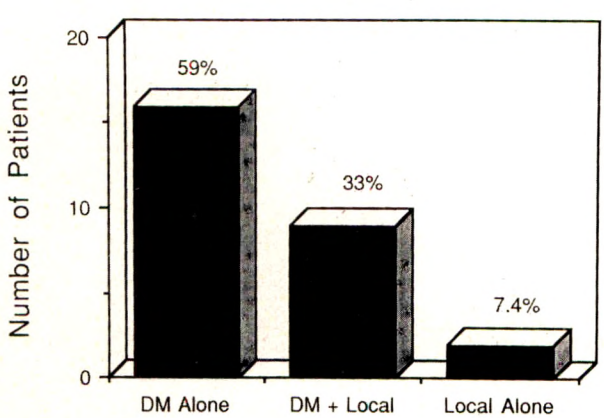

Fig. 3. Location of disease at time of death. *DM*, Distant metastases.

3). The most common sites of metastatic disease were lung (17 cases) and liver (7 cases). Other extrapelvic sites of disease included the upper abdomen, supraclavicular nodes, mediastinum, and bone.

Treatment for patients with operable disease was variable. The addition of radiation therapy did not significantly contribute to survival (Table III). Only two patients had postoperative external beam irradiation without chemotherapy; both are long-term survivors. Although nodes were not sampled in these two patients, these nodes were not suspicious at the time of operation. Four patients were treated with two courses of VP-16 and cisplatin followed by whole pelvis irradiation. Two of these also had 4500 cGy radiation treatment to the paraaortic nodes. None of the four patients has clinical evidence of disease, but all are considered to be

alive with disease because of the short follow-up period. One additional patient was treated with six courses of VP-16 and cisplatin (Table IV).

Comment

Although this study population had a relatively high incidence (3.5%) of mixed müllerian tumor in all female genital tract tumors, the past reported incidence is relatively rare.[4, 6, 9, 10] Any increase in incidence of this tumor is probably associated with increased recognition of the neoplasm. These tumors most often occur in women in the last menopausal years. The mean age of our patients (65.3 years) is consistent with other reports, with a mean age of 63 to 70 years in studies reported from European countries and the United States.[4, 6, 10-12] Of 45,342 female patients admitted to the Medical College of Georgia Hospital in a recent 4-year period, 49.6% were black. Two third of the patients in this

IB	Whole pelvis	Positive pelvic nodes	Alive with disease	9
III	No	Tumor of ovaries and in vessels	Dead of disease	18

series with mixed müllerian tumor were black. More black patients died from disease in this report than whites. Macasaet et al.[7] have suggested that mixed müllerian tumors in black women may have a different biologic origin since black women in their series tended to have more advanced disease at diagnosis. Seven percent of the patients reported herein had a history of prior pelvic irradiation. Most series report that approximately 15% of patients have a history of prior pelvic irradiation, but individual series may vary from none to 29%.[3, 4, 6-9, 11, 13] Others have also reported nulliparity to occur in from none of the patients to 32%.[4, 7-9, 12] Obesity has been noted in from 20% to 31% to two other reports.[7, 9] Patients who have appropriate staging laparotomies have almost a 35% chance of having positive retroperitoneal nodes, as reported in our series and other current reports[3, 14] (Table V).

Earlier reports on mixed müllerian tumors suggested that there may be a somewhat better outcome in patients with homologous elements only.[1, 2] However, we and other recent investigators[4, 7-9, 12, 14] found no difference in outcome between homologous and heterologous tumors. The survival (32% reported herein) continues to be dismal. Survival rates reported by others, when all stages of mixed müllerian tumor are evaluated, range from 14% to 41%.* A group of patients at high risk for failure was identified in our study and included those with vascular or lymphatic space involvement, extrauterine spread noted at the time of operative procedure, large (>5 cm) tumor bulk, and nodal metastases.

How might survival be improved? Although the number of patients in our study is small, we found no significant impact on survival when perioperative irradiation was added to surgery. Vongtama et al.[17] noted that radiation therapy was of adjunctive value to surgery in terms of decreasing pelvic recurrences and increasing survival. Salazar et al.[18] and Spanos et al.[19] also noted that adjuvant irradiation significantly improved disease controlability in the pelvis. However, other recent studies indicate no significant added benefit of adjuvant pelvic irradiation.[2, 11, 14, 15]

*References 2, 4, 5, 8, 9, 11, 13, 15, 16.

Table V. Incidence of positive retroperitoneal nodes in patients with mixed müllerian tumors

Authors	*Total No. of patients*	*Positive nodes*	
		n	%
DiSaia et al.[3]	28	10	35.7
Peters et al.[14]	13	4	31
Present series	20	7	35
Total	61	21	34.4

Preoperative irradiation could be detrimental to survival. These tumors tend to be blood-borne neoplasms. Macasaet et al.[7] strongly advocated a primary surgical approach because 55% of women with clinical stage I were found to have widespread disease at surgery; this incidence is more common than the 33% of patients in our series with clinical stage I who had extrauterine spread. Other investigators have also noted an upgrading of clinical stage I or II to more advanced disease in from 23% to 29% of patients.[13, 14] As in our series, others have reported that extrauterine spread was associated with a poor prognosis with survival rates from 0 to 28%.[5, 8, 11, 13, 19] Eighty-nine percent of our patients dead of mixed müllerian tumor died within 12 months. Spanos et al.[19] and Salazar et al.[18] noted that 90% of local and distant failures were apparent within 2 years. Shaw[11] reported that 53% of his patients died within 12 months of diagnosis. Others have also reported that when distant metastases occurred, the lungs were often involved.[6, 9, 15]

Response rates, partial or complete, are below 15% in patients with advanced or recurrent mixed müllerian tumor treated with Adriamycin alone or Adriamycin plus cyclophosphamide or dimethyl triazeno imidazole carboxamide.[20, 21] Recently Seltzer et al.[22] reported a 50% response rate in six patients treated with a combination of cisplatin and Adriamycin, with duration of response from 9 to 11 months. Gershenson et al.[23] reported a 42% response rate in patients with disseminated mixed müllerian tumor treated with cisplatin alone. Cisplatin seems to have moderate activity in this neoplasm. Kohorn et al.[13] reported an 80% survival rate

in patients who received adjuvant radiation therapy and combination chemotherapy. All of our high-risk patients treated with irradiation plus VP-16 and cisplatin are alive from 9 to 18 months after diagnosis and surgery. These patients have no apparent progression of tumor. However, the follow-up period is too short and the number of patients too small to draw any conclusions about these adjuvant modalities.

In summary, the survival in our series and others has not been improved by use of adjunctive radiation alone. High-risk factors can be identified, but only if a primary surgical approach is used to delineate the extent of disease and these risk factors. A pilot study is warranted with cisplatin-based combination chemotherapy, with or without irradiation, in these high-risk patients. All treatment modalities should be considered in women with mixed müllerian tumors of the uterus.

Discussion

Dr. R. Henry Temple, Wilmington, North Carolina, (Official Guest). In the 16-year time span of this study, the records of 41 patients with mixed müllerian tumors of the uterus were analyzed. This is a very large series of these rare and deadly tumors.

They represented 3.5% of the female genital tract tumors at the Medical College of Georgia. This is an unusually high incidence of these unusual tumors and represents a fourfold increase over what one would normally expect. Other views of the subject quote mixed müllerian tumors as representing 3% to 6% of uterine cancers.

When International Federal of Gynecology and Obstetrics criteria were applied, 61% had stage I disease, 19.5% had stage II, 2.5% had stage III, and 17% had stage IV disease. The deadly nature and dismal prognosis for this disease is reflected in the fact that there were no cures in patients with stage III or IV disease and only 12.5% of patients with stage II and 28% of patients with stage I disease were free of disease after treatment.

The demographic data presented by Dr. Gallup were generally in agreement with other large series. The mean patient age was 65.3 years, and the mean parity was 2.9. Two thirds of the patients were black; one third had diabetes. Seven percent had previous pelvic irradiation, and 9.5% had a history of previous use of exogenous estrogen. One of the few criticisms I have of this review and, indeed, of the oncologic literature in general is the failure to define the population from which the study patients are drawn. Figures that show a third of patients with diabetes mellitus or two third being black have little meaning if the prevalence of diabetes or the racial makeup of the community at large from which these patients are drawn is also unknown.

From his data, Dr. Gallup clearly delineates some very important truisms regarding mixed mülerian tumors of the uterus. They are:

1. The single most important factor signaling poor prognosis is extra uterine extension of disease. There were no survivors free of disease in the group with cancer outside the uterus.
2. In patients with disease confined to the uterus, poor prognostic factors were increasing depth of myometrial invasion, vascular or lymphatic space involvement, and large tumor bulk (>5 cm) even without myometrial invasion. The correlation between bulk of tumor and prognosis is one not appreciated in most other reviews of the subject.
3. Finally, surgery is the mainstay of treatment. Only surgery seems to make any difference incure rates. Neither adjuvant radiation nor chemotherapy significantly increased cure rates. Furthermore, their effect on length of survival is uncertain.

Somewhat as an addendum, the paper describes five patients treated with cisplatin and VP-16. One patients with stage III disease was dead of disease 18 months after treatment. The other four (two patients with stage IB and two with stage II disease) were described as alive with disease 9 to 15 months after treatment. On the basis of these results, the paper calls for a pilot study using cisplatin-based combination chemotherapy for high-risk patients.

In closing, I would like to pose some questions. Although there have been several previous studies pointing out cisplatin's possible activity in mixed müllerian tumors, the role of VP-16 has not been reported. How was this agent chosen?

Was there a control group for the group treated with cisplatin and VP-16? What might be the expected natural course of the disease in similarly matched stage IB and II patients not treated with chemotherapy?

Dr. Gallup (Closing). I appreciate Dr. Temple's kind comments. I again apologize for the slight change in the numbers. After review of re-cut slides on one patient, she was dropped from the study group; this left 40 patients for analysis. He is correct in his criticism about our failure to more clearly define the overall population makeup of our study group. We presented a group of patients who underwent running midline incision closures at the annual clinical meeting in May last year. Of those Medical College of Georgia patients, 54% were black and one third had diabetes mellitus.

Why did we choose VP-16 and cisplatin as chemotherapeutic agents? We have treated a group of about 15 patients with ovarian carcinoma and failed treatment with cisplatin-based chemotherapy, with second-line VP-16 and cisplatin. We have had significant long-term responses, some of which were complete, in this group. One of these long-term responders had a primary mixed mesodermal sarcoma of the ovary. We did not have a matched control group, but no patients with clinical stage I or II disease who had positive nodes and did not receive VP-16 and platinum are survivors.

I agree with Dr. Underwood that we should try to give chemotherapy as soon after surgery as possible.

Evaluation of surgical staples in cesarean section

Gene Burkett, MD, L. P. Jensen, MD, A. Lai, MD, M. J. O'Sullivan, MD, S. Yasin, MD, S. Beydoun, MD, and A. G. W. McLeod, MD

Miami, Florida

Experience with Lactomer absorbable surgical staples (Auto Suture Poly CS 57 disposable surgical stapler) in 62 cesarean sections was compared with an equal number of operations performed with standard techniques. The technique of appliciation of the stapler evolved with experience. Countertraction to staplers with Allis' clamps prevented uterine V incisions. Operative time was longer for the stapled suture group for primary cesarean sections, but was unchanged for repeat procedures. Excellent hemostasis of the uterine incision was achieved even when varicose sinusoidal veins were present. Significant reductions of hemoglobin deficits from 2.16 to 1.3[illegible] gm/dl, postoperative anemia from 29% to 6.4%, and endometritis from 22.5% to 6.4% occurred respectively in nonstapled and stapled groups. A reduced hospital stay, shortened by 2.1 days, saved each patient $2950. Blood loss estimates by surgeons or anesthetists were often at variance. Surgeons' acceptance of the procedure grew with experience. On the basis of these results, use of absorbable staples offers certain advantages in reducing blood loss, infection, and hospital stay in cesarean deliveries. (Am J Obstet Gynecol 1989;161:540-7.)

Key words: Absorbable staples, cesarean section

Surgical stapling has undergone major modifications since it was first introduced in the United States in the early 1960s. Early staples were made from stainless steel, and complications such as infection and dyspareunia were frequently reported after hysterectomy and vaginal vault stapling.[1-3] Removal of the staples was almost mandatory. Major modifications to the material of the staples has led to widespread acceptance of stapling in many surgical specialties, especially in vascular, gastrointestinal, and genitourinary surgery, and gynecologically, especially in abdominal and vaginal hysterectomy.[4-9] In cases of malignant disease of female genital organs, several reports have related reductions in blood loss and operating times to the use of absorbable staples.

The most significant modification was the change to absorbable suture material. Currently glycolide-lactide copolymer (Lactomer* absorbable surgical staples) is used, which in gynecologic patients has resulted not only in reduction in operating time but also in lower postoperative morbidity as infections, granulomas, and in chronic dyspareunia.[9-11] Postoperative stay and hospital costs have decreased.[10] Removal of visible staples in the vaginal vault is now rarely necessary and a resurgence of interest in their use has surfaced.

The progression to obstetric use of surgical staples for abdominal delivery of the infant seemed reasonable since bleeding from the incision of the highly vascular gravid uterus could be easily curtailed. The speed, safety, and convenience of the stapling device to open the uterus were also attractive incentives.[12] In experiments with nonhuman primates, problems of infertility caused by migration of metal staples were no longer a risk with the modern copolymer counterparts.[12, 13]

Retrospective analysis of our experience developed out of need to assess the efficacy and cost of the absorbable staple (Auto Suture Poly CS* 57 disposable surgical stapler) in cesarean section, especially because the cost of sutures in nonstapling techniques seemed so much less. The findings of this audit are reported in this article.

Material and methods

The hospital records of 62 patients who were delivered by cesarean section in which absorbable staples (Auto Suture Poly CS 57 disposable surgical stapler) were used to open the uterine incision were compared with 62 patients whose cesarean sections were performed by standard nonstaple techniques with scissor and sutures. The comparison group was chosen by reviewing the records of the next cesarean section following the case done by surgical stapler.

All patients were delivered at the University of Miami/Jackson Memorial Medical Center between June 1986 and April 1987. Demographic data were collected

*Reg. U.S. Patent and Trademark Office. Auto Suture Company, Div. of United States Surgical Corporation, Norwalk, Conn.

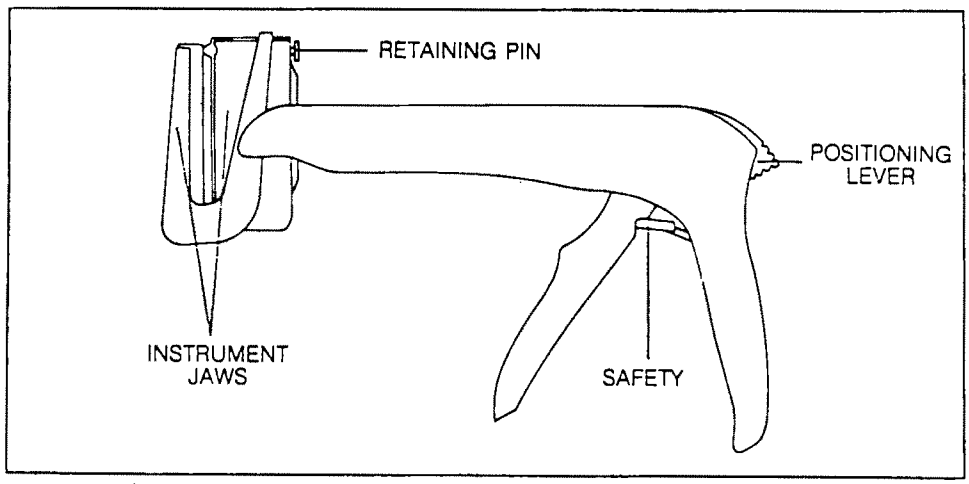

Fig. 1. Schematic view and nomenclature of Auto Suture Poly CS 57 disposable surgical stapler.

from each group on age, parity, race, gestational age, indication for cesarean section, labor or nonlabor, number of vaginal examinations in labor, rupture of membranes (length of time), and type of uterine incision.

Outcome variables were related to blood loss as estimated by surgeons, hemoglobin deficits (calculated from differences of hemoglobin at admission and discharge), and anemia (hemoglobin <10 gm/dl at discharge). Postoperative infection (febrile morbidity, temperature ≥100.4° F) and length of hospital stay were also compared. The acceptance of the procedure was gauged by comments of each surgeon after the first use of staples and later after 62 cases had been completed.

Method of application of the staples initially was that recommended by the manufacturers but quickly evolved with modification to avoid V-shaped incisions in the uterus. To easily accommodate the instrument under the abdominal wall, a small Richardson's retractor was used to elevate (rather than a lateral pull) the abdominal wall. A transverse incision of 1 to 2 cm is made with a knife in the central part of the uterus in the usual way for any cesarean section.

The Auto Suture Poly CS 57 disposable surgical stapler was applied to extend the incision laterally on both sides of the uterus. The following steps were taken (Fig. 1).

1. The jaws of the instrument are parted by opening the positioning lever.
2. The lower jaw of the stapler is passed through the initial incision in the uterus with fingers between the fetus and instrument. Use of Allis' clamps on the initial uterine incision provides countertraction and rotates the uterus so that the stapler can be applied straight or only very slightly inclined upward. In this way V-shaped uterine incisions are avoided. The technique of protecting the fetus is the same as that when the uterine incision is extended with the bandage scissors.
3. The positioning lever of the instrument is closed so that the instrument is locked in place and the position is rechecked. It is important to check that no inappropriate structures, such as fetal parts, are within the jaws of the instrument. Tissue is only incised if the stapler is fired.
4. Release of the safety guard allows the trigger to be pressed firmly toward the handle (as far back as possible). This will fire two rows of eight staples per row from each jaw, so that the upper staples lock into the lower staples, compressing the tissue between the staples. At the same time that the staples are fired, a knife blade cuts the uterine segment between the two rows of staples. The uterine incision now has a row of staples on the upper and lower edges and hemorrhage is controlled. Actual measurements of the two sizes of staples available are a height of 0.140 inches (3.6 mm) or 0.170 inches (4.3 mm) when closed, and the width (6.2 mm at the top and 6.6 mm at the bottom) is the same for each size.

Closure of the uterine incision is accomplished with a single-layer continuous suture of chromic catgut 0. As the method evolved, polyglycolic suture 0 was substituted for the catgut. At first the incision was closed by suturing completely around the staples, but apposition of the staples on each side of the incision was better achieved by passing the suture through the middle of each locked staple pair. Finally, the complete evolution resulted in alternating one stitch through the staples for proper apposition with the next stitch around the following staple pair to suture full thickness of the uterine musculature.

In the nonstapled cesarean sections, closure of the uterine incision was done by two continuous layers of either chromic catgut 0 or polyglycolic 0; the first layer was hemostatic and full thickness, while the second was an invaginating watertight seal. Suture material was chosen by the surgeon.

*More than one indication in some patients.

Statistical analysis was done by Student's t test for the nonstapled pairs versus stapled groups. Evaluation of cesarean section by labor/nonlabor, primary/repeat operation was by χ^2 analysis. The χ^2 analysis was used to compare postoperative anemia and endometritis. Fisher's exact test was used in analysis of single and multiple pregnancies.

Results

Records of 62 patients who had cesarean section with the use of absorbable stapler-knife hysterotomy were compared with an equal number of patients whose operations were done by standard nonstaple techniques.

Demographic data in Table I indicate that age, parity, and race of the two cesarean groups (stapled and nonstapled) were approximately the same. There were no significant differences in the number of elective cesarean sections or cesarean sections after labor. However, the number of primary cesarean sections was significantly more in the nonstapled group (χ^2, 5.629; *df*, 1; p = 0.02). The mean number of vaginal examinations during labor was the same in each group. The range of vaginal examinations was zero to nine in the nonstapled group and zero to eight in the stapled group. Uterine incisions were predominantly transverse lower uterine incisions, and the gestations were primarily singleton pregnancies.

Indications for cesarean sections are listed in Table II and did not differ between the two groups. Previous cesarean sections and cephalopelvic disproportion predominate as the usual indications for cesarean section. Among the indications listed as "other" are previous myomectomy (2 cases), active lupus (1), severe intrauterine growth retardation (3), severe preeclampsia with deteriorating HELLP syndrome (hemolysis, elevated liver enzymes, low platelets) (3), placenta previa (1), rhesus isoimmunization (2), diabetes mellitus (3), and twins in breech-vertex presentation (2). More than one indication occurred in many patients.

Table III shows the outcomes of the cesarean sections of each group.

The operating time from first incision to placement of the last skin staple or suture was significantly different between the stapled and nonstapled group in primary but not in repeat cesarean sections. However, the mean surgical operating time when *all* cesarean sections were considered, irrespective of the group, was 41.4 minutes (n = 73) for primary and 45.2 minutes

Table III. Outcome of cesarean section

*For column, $t = 2.38$; df 60; $p < 0.02$.
†$\chi^2 = 10.83$; df 1; $p < 0.001$.
‡$\chi^2 = 6.50$; df 1; $p < 0.01$.

(*n* = 51) for repeat cesarean sections, indicating statistically longer intervals for repeat cesarean sections ($p = 0.04$).

Estimated blood loss by surgeons and anesthetists was significantly different; larger volumes were reported by anesthetists (*t* test, 29.2; *df*, 0.61, $p = 0.0001$). Between nonstapled and stapled groups, the estimated blood loss by the surgeons was statistically higher in the nonstapled group, whereas estimation by the anesthesiologists (also significant), was in the opposite direction, that is, higher in the stapled group.

Conversely, hemoglobin deficits calculated from hemoglobin at admission and hemoglobin on the third postoperative day showed that the mean hemoglobin deficit was significantly lower in the stapled group than in the nonstapled group (2.16 vs. 1.31 gm/dl). By comparison, the mean deficit in 40 vaginal deliveries was 0.9 gm/dl (vaginal delivery vs. cesarean section in both groups, $p < 0.001$ χ^2, stapled vs. nonstapled, $p < 0.00001$, *t* test). Postoperative hemoglobin of ≤10 gm/dl was present in 18 (29.0%) patients in the nonstapled group and only in four (6.4%) patients in the stapled group. Preoperatively six patients of the nonstapled group and three from the stapled group had admission hemoglobin levels of ≤10 gm/dl. Therefore blood loss at operation would account for postoperative anemia in 12 nonstapled and one stapled patient and is statistically significant ($p < 0.001$).

Postpartum infection included endometritis in 14 (22.5%) patients in the nonstapled group versus 4 (6.4%) in the stapled cesarean section patients; urinary tract infections occurred in two patients in the nonstapled group.

As a result of the increase in endometritis, the mean postoperative hospital stay was significantly higher in the nonstapled group (6.9 vs 4.8 days); thus patients in the stapled group spent 2.1 days less in the hospital. The range of stay for the nonstapled group was 4 to 15 days, whereas for the stapled group it was 3 to 8 days. This reduction in postoperative stay resulted in a savings of $2950 (daily hospital cost, excluding cost of staples $1500/day times 2.1 days minus extra cost of staples, $200) per patient.

Angular tears were similar in each group. In two cases the staples did not close properly and compression of the uterine incision was not accomplished. Four patients reported passing staples between 3 and 6 weeks post partum, and one patient passed staples on several occasions over a 2-week interval.

Opinions of the surgeons using the Auto Suture Poly CS 57 disposable surgical stapler were recorded after the first use of the instrument and after completion of the 62 stapled cesarean sections. All evaluations were sought before analysis of all data. Initial comments were approval by two surgeons, disapproval by three, and three were unsure. Six surgeons approved the use of the stapler in selected cesarean sections after 62 cases with stapled sutures were completed. These indications included lower uterine segments with multiple large veins, thick lower uterine segments, possibly in anterior placenta previa. Two surgeons continued to have doubts about the usefulness of the stapler; one surgeon

believed that this was particularly disappointing because the staples were not thick enough to encompass and compress the thick uterine muscle of the classical incision. In his case, staples tore off the edge of the incision as soon as applied.

Female surgeons also complained that pressure necessary to squeeze the trigger to fire the staples required both hands and increased the degree of difficulty in application, whereas residents complained that stapling "slowed them down."

All agreed that hemostasis, and consequently visibility, of uterine incisions was excellent and better than in the nonstapled group.

Comment

The Auto Suture Poly CS 57 disposable surgical stapler was approved by the Food and Drug Administration for use in hysterectomy and cesarean section on the basis of animal studies and the experience of the use of absorbable staples in other specialties. It was expected that these staples would reduce blood loss and operative and postoperative morbidity, as had occurred when they were used in other specialties. However, the cost was far in excess of the suture material required for standard techniques of cesarean section, and therefore an audit to determine the efficacy of the knife-stapler was undertaken. The trends suggested from this data strongly support a reduction in blood loss and postoperative morbidity. No apparent gain in operating time was achieved. On reflection, the technique varies little from that of the standard method for opening the uterine incision.

Blood loss calculations in cesarean sections provide many difficulties. Significant variations of the estimates for blood loss by the anesthetist and surgeon emphasize the unreliability of that method. Differences varied statistically, and the trends were in opposite directions between the two groups of patients. However, in combination with the vital signs of the patients, such clinical estimates continue to be important in intraoperative assessment of blood loss. The accuracy of such estimates is amplified by contamination with amniotic fluid, blood soaked into operating drapes, sponges, and perhaps even on or under the operating table. However, a most important consideration is that blood lost in this operation includes not only that from the uterine incision but also a large amount from the placental site and a small amount from the abdominal incision. The knife-stapler can only affect blood loss associated with the uterine incision.

To circumvent some of these difficulties, we decided to compare the hemoglobin at admission with that of the third postoperative day. Previous analysis had indicated that hemoglobin concentrations and fluid shifts associated with delivery were usually stable by the third day. Since expected blood loss at cesarean section does not usually require replacement by transfusion, the third-day estimation of hemoglobin concentration allows the surgeon to evaluate surgical morbidity and decide whether or not blood loss at surgery necessitates any further treatment. The data show that autosuture stapling plays a role in the reduction of blood (on the basis of lower mean hemoglobin deficit of 2.16 gm/dl for the nonstapled group and 1.31 gm/dl for the stapled group). The mean deficit for vaginal deliveries of 0.9 gm/dl probably indicates the loss of blood from the placental site and brings into perspective the values obtained from patients who were delivered surgically.

The larger number of patients with postoperative anemia in the nonstapled group (29% vs. 6%) follows the trend seen with the hemoglobin deficit analysis and strengthens the concept that stapling reduces blood loss.

The postoperative incidence of endometritis and urinary infections was less common in the women with stapled cesarean sections (6.4%), than in the nonstapled group (22.5%). There is no immediate explanation for this wide variation since the patients were from the same pool of a lower socioeconomic group in a multiethnic, inner-city hospital. In a separate additional audit of 35 consecutive cesarean sections, seven cases (20%) with perioperative mild to severe endometritis indicated that the findings in our study group were not a chance cluster, which would falsely elevate the incidence in our comparison nonstapled group. The difference in the incidence of endometritis in the two study groups may be partially a result of the material used for the staples, a glycolide-lactide copolymer, which is more inert than other suture material used in the nonstapled group and therefore may be less enhancing to infection.

However, this incidence of postoperative endometritis is unexpectedly high, even for our hospital. This is particularly so because of the use of prophylactic antibiotics for all patients who labor before cesarean section. Mefoxin irrigation of the uterine cavity, uterine incision, and the abdominal incison has proved efficacious in our institution for the past 5 years, and the incidence of postoperative endometritis has been reduced from 33% to 6%.[14] An incidence of 22.5% on the nonstapled group, or 20% in the group of consecutive cesarean section which was audited separately, is therefore surprising and unexplained.

Complications were few, but the most disconcerting to the patient was the passing of the staples vaginally. It is therefore important that the patients be alerted that as the staples dissolve and loosen, particles may be extruded usually at 3 to 6 weeks after operation, as occurred in four patients. Bleeding from the angles of

the uterine incision occurs with the stapler because of a pin in the instrument that fixes it in place once the stapler is closed. After the stapler is removed, bleeding often occurs from the site of the pin. In the nonstapled cesarean sections, incursions into the uterine vessels when the uterine incision was extended too far laterally resulted in bleeding at the angles of uterine incision. Extension tears of the uterine incisions occurred evenly in both groups and can be attributed to technical errors.

No fetal injury was encountered in our study. We believe that this is largely a result of our insistence that a protective finger must be inserted between the fetus and the undersurface of the uterus whenever any instrument, scissors or stapler, is used to extend the initial uterine incision laterally. This is also done in performing an episiotomy. There is no room for compromise on this maneuver, and anecdotal reports of severed fetal digits can only be attributed to poor surgical techniques rather than instrument failure. Beresford[9] emphasizes that tissue damage will not occur until the stapler is fired; therefore a recheck on position and the tissue that is gripped can prevent fetal injury. It is possible that a short period of training may be necessary for each obstetrician to become familiar with use of the instrument. This will enhance versatility in usage and will certainly minimize the risk of serious complications. As the surgeons in our group gained experience with the stapler, their confidence grew and led to acceptance of the instrument. The opinions of two surgeons from another hospital changed from skepticism to resounding approval.

Finally, the savings of hospital costs of $2950 per patient (the reduced hospital stay of 2 days seemingly related to the lower incidence of endometritis) should encourage acceptance of surgical staples for use in cesarean sections. Our observations lead us to believe that routine stapling may not be practical, but candidates selected for application would include those cases in which multiple uterine sinusoid-like vessels occupy the desired incision site or where the lower uterine segments are thick, or some cases of placenta previa in which lower segment incisions are possible, and in patients in whom long labors have been unsuccessful for a vaginal delivery.

Currently a randomized trial is in progress to verify these findings and to carefully determine by protocol the role of staples in cesarean section, but this audit of a relatively costly instrument even retrospectively suggests trends to reduction of blood loss, lowered postoperative morbidity, and decreased hospital stay. Concurrently it also raises questions with regard to future pregnancies and vaginal delivery after cesarean section performed with the absorbable staple–knife instruments. Long-term follow-up of such patients should be performed.

Discussion

Dr. J. Terrell Pope, Macon, Georgia (Official Guest). Dr. Burkett has presented data from a retrospective audit of 62 cesarean sections using copolymer surgical staples. This surgical instrument was introduced in 1987. We are indebted to Dr. Burkett and his colleagues for providing the first clinical data on the use of staples in cesarean section. Since absorbable staples cost $200 versus $2 to $4 for conventional sutures, their efficacy needed to be established.

In this study use of the staples suggested two trends: first, a significant reduction in blood loss and second, a significant decrease in the incidence of postoperative endometritis, thereby reducing hospital stay. This resulted in substantial cost savings. The study did not support the finding of a shortened operative time using absorbable staples, as has been shown in other operations in gynecology and other specialties.

Difference in blood loss between the two groups was significant. The hemoglobin deficit was used by Dr. Burkett to eliminate the subjective estimates by surgeons and anesthesiologists. Brant[1] and Wilcox et al.[2] found average blood loss at cesarean section to be 1000 ml. This study supports their findings since the nonstapled group had a hemoglobin deficit of 2.16 gm/dl, which represents approximately 1080 ml blood loss

(1 gm of hemoglobin deficit = 500 ml of blood loss). Blood loss in the stapled group was 565 ml, compared with 450 ml blood loss at vaginal delivery. These findings suggest that blood loss from the hysterotomy incision alone with conventional technique is approximately 500 ml. From a cost-saving standpoint, it would be interesting to know if any of the 22 patients (18 nonstapled and four stapled) with postoperative anemia required transfusion.

Postoperative endometritis was significantly lower in the stapled group (6.4% vs. 22.5% in the nonstapled group). Assuming that the same criteria were applied to both groups to make the diagnosis and that essentially the same percentage of patients received prophylactic antibiotics, what accounted for this significant discrepancy between the two groups? Can difference in surgical technique alone explain this discrepancy? Although socioeconomic status, number of vaginal examinations, internal fetal monitoring, anemia, obesity, prolonged operating time, and type of anesthesia have all been identified as risk factors for postoperative endometritis, prolonged labor and prolonged rupture of membranes are generally considered to be the most important factors.[3] Certainly, it would be relevant to compare both groups using these two variables. Moreover, Green and Sarubbi[4] and Kreutner et al.[5] found no increase in febrile morbidity in elective repeat cesarean sections. Fifty-one percent of the stapled group had repeat cesarean sections. If most were done electively, one would predict a lower postoperative infection rate in this group. Eight different surgeons used the staples. Did the same surgeons or colleagues at their same level of training perform the 62 sections using conventional technique? Miller et al.[6] recently reported that postoperative endometritis is significantly increased when surgery is performed by residents below the third-year level. If postoperative endometritis remains significantly lower with staples after the two groups are compared for duration of labor, duration of ruptured membranes, number of elective repeat cesarean sections, and the level of surgical training, then their use would seem efficacious.

Finally, will the myometrial scars produced by use of copolymer staples withstand the rigors of labor as vaginal birth after cesarean section becomes common? Will dissection of the bladder flap be more difficult? McNeeley et al.[7] compared copolymer staples with chromic suture during hysterectomy in the animal model and found more extensive necrosis and exudate with increased adhesion formation using the staples.

In summary, despite my questions arising from the retrospective nature of this study, Dr. Burkett and his colleagues have provided us with important clinical information on the use of a new surgical instrument that decreased blood loss from the hysterotomy incision in cesarean sections. Postoperative endometritis appears to be lowered with use of staples. I look forward to learning the results of his randomized study and to the reports on long-term follow-up of these patients.

DR. JOHN W. C. JOHNSON, Gainesville, Florida. I enjoyed the details of Dr. Burkett's study. He omitted the outcome for one of the patients, the fetus. There have been reports in the lay literature of a fetal finger being amputated with the use of this clamp. I am sure this did not occur in Miami, but I would like Dr. Burkett to reassure us that all the infants did well and there were no morbidity problems with the infants.

DR. BURKETT (Closing). First I'll answer some of Dr. Pope's questions. We do not routinely use transfusions on cesarean sections. Generally, although we reported anemia under 10 gm in up to 29%, we do not use transfusions unless the patient is very anemic and symptomatic. In the prospective series, we have at least one patient who developed disseminated intravascular coagulation from obstetric complications and who was transfused, but we will report on that later.

The more important question posed by Dr. Pope was the etiology of postoperative endometritis. We tried to evaluate this, but with only 18 patients the numbers are so very small when broken down by variables that we could not reach a conclusion as to whether any of the factors he mentioned were in fact causal. We really do not know why there is a higher incidence of endometritis in the nonstapled group. To ensure that this was not a chance cluster, we studied 35 consecutive cesarean sections about the same period and found that the incidence of endometritis was almost as high, 22.5%. We may have been going through a period when we were not attentive enough to prevention of infection. We routinely use prophylactic antibiotic irrigation in the uterus with 2 gm of Mefoxin (1 gm injected into the cavity, 0.5 gm on the uterine incision, and 0.5 gm in the abdominal incision). This study was reported by Jensen (one of the co-authors) et al. (see reference 14 of article), and postoperative infection rates were lowered to acceptable levels of approximately 8% to 10%.

With regard to the experience of the surgeons, certainly the use of the staples was not entirely confined to our authors. That may be one factor in cause of

infection that we cannot adequately control because we must expose our residents to this experience. The residents usually were third-year or chief residents, and usually there was an attending physician present at the cesarean section. However, one aspect we have not mentioned here is that the negative or positive attitudes of surgeons to the new instrument varied considerably and influenced the decision for use of the staples and possibly its acceptance.

In terms of vaginal birth after cesarean section, currently we don't have the answer. We will obviously have to do follow-up and carefully evaluate these patients. Certainly because glycolide-lactide copolymer material causes less tissue reaction, then there should be less fibrous tissue in the uterine incision and less weakness.

Dr. Johnson, there were no fetal injuries. We insisted that in any instrumentation like an episiotomy or uterine incision with bandage scissors or the stapler that a protective finger be inserted between the instrument and the fetus. In the anecdotal report from Minnesota, this surgical axiom was not practiced. There is one other case that I know occurred in Houston; again the same circumstances occurred: care was not taken to protect the fetus.

Finally, concerning the clumsiness of the instrument, we have reported to the manufacturers that redesign is necessary and they are responding to that situation.

Outpatient triplet management: A contemporary review

Roger B. Newman, MD, Cheryl Hamer, RN, BS, and M. Clinton Miller, PhD
Charleston, South Carolina

The antepartum management of 198 women who were delivered of triplets between 1985 and 1988 is reviewed. Women were managed with the assistance of ambulatory perinatal nursing to provide outpatient surveillance. Modified bed rest, prophylactic tocolysis, and betamethasone were liberally used and patients were hospitalized only when obstetrically indicated. The most common antepartum complication was preterm labor (66.2%) and the success of therapy with tocolytic agents is described. The mean gestational age and birth weight at delivery were 33.6 ± 3 weeks (mean ± SD) and 1871 ± 555 gm, respectively. Comparison of the gestational age distribution at delivery with previous reviews demonstrates fewer deliveries <29 weeks' gestation and significantly more deliveries between 32 and 37 weeks' gestation. Cesarean delivery occurred in 94% of the triplets, which eliminated birth order as a factor that affects survival. The corrected perinatal survival rate was 95% in this contemporary review of outpatient triplet management and represents a major improvement in the expected outcome for triplets. (Am J Obstet Gynecol 1989;161:547-55.)

Key words: Triplets, outpatient management, ambulatory nursing, perinatal survival

In 1958 Geza Kurtz[1] prefaced his excellent review of the factors that influence triplet survival with the following, "Because of the rarity of triplet birth the human interest appeal of such an event is greater than its practical significance." In 1989, however, advances in reproductive biology necessitate a reevaluation of this statement. Ovulation induction agents have dramatically increased the observed frequency of triplet birth in the most recent reviews.[2-6] Unfortunately, these reviews are limited by either their small size or the prolonged period of time required to achieve a reportable number of cases. Obstetricians are challenged by an increasing incidence of triplet pregnancies without adequate information on which to base management decisions and to evaluate outcome. The following large series of women who were delivered of triplets between 1985 and 1988 is presented to describe changing trends in the management of triplets and the dramatically improved prognosis of these high-risk pregnancies.

Causes		
Spontaneous	102	51.5
Induced	82	41.4
In vitro fertilization	14	7.1

Table II. The duration of therapy with tocolytic agents in 131 triplet pregnancies with preterm labor

Duration of therapy	*No.*	*%*
Noncandidate for therapy*	38	29.0
Tocolytic therapy < 48 hours	13	9.9
Tocolytic therapy 2 to 7 days	12	9.2
Tocolytic therapy < 7 days	68	51.9

*Preterm premature rupture of the membranes, advanced cervical dilation with intact membranes, and elective preterm delivery.

all referred for ambulatory perinatal nursing provided by the Tokos Medical Corporation at 24 regional centers across the country. The busiest regional center was in Orange, Calif., which managed 23 patients during the study period, whereas centers in Detroit, Charlotte, N.C., and Minneapolis managed the fewest at two each. Only four of the regional centers (Orange, San Francisco, Philadelphia, and Tampa) followed-up more than 15 patients during the study period. Individual patient management was at the discretion of a large number of attending obstetricians in both private and academic practices.

Through the involvement of ambulatory nursing personnel, each patient was contacted daily by telephone to (1) assess maternal symptomatology as it may relate to preterm labor; (2) provide education and reinforcement of preterm birth prevention principles; (3) assess patient compliance with physician-directed treatment plans; (4) perform uterine activity monitoring 2 hours daily with a portable tocodynamometer designed for outpatient use[7]; (5) provide a liaison between the patient and physician available 24 hours a day, 7 days a week; and (6) provide emotional support and patient advocacy. In addition, a daily patient-care log was maintained in which alterations in antepartum management, hospitalizations, secondary diagnoses, delivery, and neonatal outcome data were carefully recorded. Retrospective analysis of these patient-care records provided the management and outcome data reported in this review. Patient data sheets were coded to ensure patient confidentiality.

Daily ambulatory nursing contact and uterine activity monitoring began at an average gestational age of 23.8 ± 3.3 weeks (mean ± SD) and continued until 32.6 ± 3.2 weeks. When patient symptomatology or objectively recorded uterine activity exceeded physician-prescribed criteria, the perinatal nursing service would immediately contact the referring physician. In the event of hospitalization, the ambulatory nursing service was kept advised of the patient's progress and resumed daily contact if the patient was discharged undelivered.

The length of gestation was established based on the date of in vitro fertilization or medically induced ovulation when known. In spontaneous triplets, the gestational age was determined based on the date of confinement estimated by obstetric and ultrasonographic criteria. All triplet gestations were known at the time of their referral for ambulatory nursing surveillance.

Preterm labor was diagnosed when excessive uterine activity was accompanied by progressive cervical dilation or effacement at <37 completed weeks' gestation. Premature rupture of the membranes at <37 completed weeks' gestation was also considered preterm labor. Hospitalization because of increased uterine activity without associated cervical change was considered threatened preterm labor. Hospitalization without either increased uterine activity or cervical change was considered observatory unless other specific maternal or fetal complications were identified.

A variety of tocolytic agents were used both therapeutically and prophylactically at the discretion of the referring obstetrician. Intravenous magnesium sulfate was the most common agent administered for treatment of preterm labor. Oral β-adrenergic agents (terbutaline sulfate and ritodrine hydrochloride) were commonly given for both prophylaxis and maintenance therapy to prevent recurrent preterm labor. The duration of successful therapy with tocolytic agents was calculated on the basis of the number of days between the first episode of documented preterm labor and the date of delivery.

The primary indication for delivery was carefully sought in each case. Deliveries were considered to have been elective if they occurred without benefit of labor or other maternal-fetal complications that required delivery. Cases of early preterm labor (cervical dilation <4 cm) with intact membranes in which tocolysis was not used but would have been a reasonable alternative were also considered to be elective deliveries. Indications for preterm delivery included advanced preterm

labor (cervical dilation ≥4 cm and tocolysis was not considered a reasonable alternative), preterm labor with failed tocolysis, and preterm premature rupture of the membranes. Rupture of the membranes or the onset of regular uterine contractions after 37 completed weeks' gestation was considered term labor. Maternal or fetal indications for delivery were based on the clinical impression of the referring obstetrician.

The stillbirth rate was defined as a fetal loss at ≥20 weeks' gestation or weight ≥500 gm. The neonatal death rate was defined as the death of a liveborn infant within the first 28 days after birth. The perinatal mortality rate was the summation of the stillbirth and neonatal death rates. The corrected perinatal mortality rate included those stillbirths and neonatal deaths beyond 24 weeks' gestation and excluded those infants with lethal congenital anomalies.

Data are presented as means ± SD. Statistical comparisons were performed with the unpaired Student's t test and the χ^2 test where appropriate.

Results

The demographic and causal characteristics of the 198 triplet gestations in this review are presented in Table I. Almost half of the triplets in this review were a result of either in vitro fertilization or medical induction of ovulation.

The goal of antepartum management in this series was to provide obstetric surveillance on an outpatient basis. Almost all patients were prescribed some degree of bed rest or activity restriction in addition to ambulatory perinatal nursing. A total of 115 patients (58.1%) were placed on prophylactic tocolytic therapy by their referring obstetrician, and seven women (3.5%) were managed with the aid of a cervical cerclage. Therapy with corticosteroids for the enhancement of fetal lung maturation was used in most cases of preterm labor <34 weeks' gestation.

Despite a goal of outpatient management, 88 women (44.4%) required antepartum hospitalization on 110 occasions for reasons other than preterm labor. The most common indications were threatened preterm labor (51%), observation (20%), and pregnancy-induced hypertension (15.5%). The average duration of stay for each antepartum hospitalization was 15.2 ± 15 days.

In addition, 131 of the triplet pregnancies (66.2%) had preterm labor at an average gestational age of 29.9 ± 3.5 weeks. The success of therapy with tocolytic agents in the inhibition of preterm labor is described in Table II. The mean time gained in utero for those women who received therapy with tocolytic agents was 25.6 ± 22 days. However, 174 women (87.9%) still were delivered of their triplets at <37 completed weeks' gestation.

The indications for delivery are identified in Fig. 1.

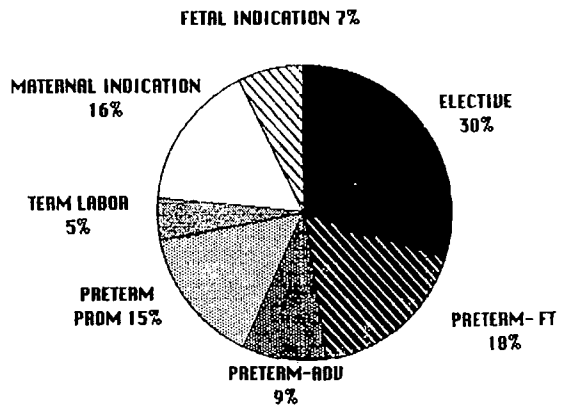

Fig. 1. Distribution of indications for delivery among 198 triplet gestations. Fetal indications include intrauterine fetal demise (4), intrauterine growth retardation (3), placental abruption (3), and fetal distress (4). Maternal indications include pregnancy-induced hypertension (28), pulmonary edema (2), abdominal pain (1), and chorioamnionitis (1). (*FT* = failed tocolysis; *ADV* = advanced cervical dilation and effacement; *PROM* = premature rupture of membranes.)

Premature rupture of the membranes is not always an indication for delivery; however, of the 30 women with preterm premature rupture of the membranes, 25 were delivered of infants on the same day that rupture of the membranes occurred. Three more women were delivered within 48 hours and the remaining two were delivered within 72 hours. Fifty-nine women (29.8%) were delivered electively by their obstetricians; 35 of those were premature (<37 weeks' gestation) and the remaining 24 were at term. Fig. 2 presents the gestational age distribution at which these elective deliveries occurred. Fig. 2 also indicates which of these deliveries were preceded by preterm labor at an earlier point in gestation (19) and those uncomplicated by prior preterm labor (40). In only five of the 19 elective deliveries complicated by prior preterm labor did this labor immediately precede delivery. The preterm labor in these five cases was considered early enough that therapy with tocolytic agents would have been considered a reasonable treatment alternative.

Cesarean section was the mode of delivery in 186 cases (93.9%). Nine women (4.6%) were delivered vaginally whereas another three (1.5%) were delivered of the first infant vaginally but required emergent cesarean delivery because of intrapartum complications.

The average gestational age at delivery was 33.6 ± 3 weeks and the mean birth weight was 1871 ± 555 gm. Only 13 women (6.6%) were delivered at <29 weeks' gestation and only nine (4.5%) were delivered at >37 weeks' gestation. A total of 149 women (75.3%) were delivered between 32 and 37 weeks' gestation. Comparison of the gestational age distribution at delivery with several previously reported reviews[1-3, 8-10] reveals

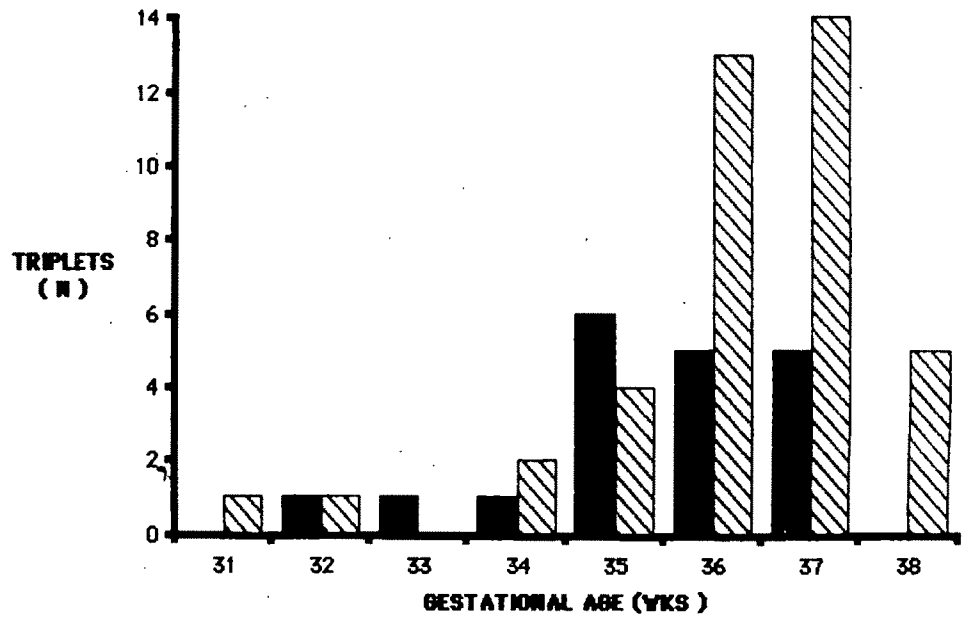

Fig. 2. Number of triplet gestations (n = 59) delivered electively between 31 and 38 weeks' gestation. Pregnancies (n = 19) previously complicated by premature labor *(black bars)* are differentiated from gestations (n = 40) uncomplicated by preterm labor *(striped bars)*.

significantly fewer deliveries at the extremes of gestational age in the current report and a greater number of deliveries clustered between 32 and 37 weeks' gestation (Fig. 3). There was no improvement in the gestational age at delivery (33.8 ± 2.8 weeks) or birth weight (1894 ± 486 gm) for the 115 women who received prophylactic tocolysis, as compared with the 83 women who did not receive these medications (33.2 ± 3.5 weeks and 1869 ± 518 gm). Of the seven women who received a cerclage, most were placed after the discovery of very early cervical change. The outcome for these women was generally poor with an average gestational age at delivery of 29.2 ± 4.1 weeks and a birth weight of 1271 ± 489 gm.

There were 19 stillbirths (3.2%) among the 594 triplets in this series. Among the 575 liveborn infants, there were 421 (73.2%) admissions to neonatal intensive care units and respiratory distress syndrome was diagnosed in 131 (22.8%) infants. There were 20 neonatal deaths (3.5%) in this review. Correction of these mortality rates to exclude nine triplets delivered <24 weeks' gestation (all delivered at 22 weeks' gestation; six stillbirths, three neonatal deaths, and a birth weight range of 430 to 510 gm) and one triplet with a lethal congenital anomaly (hypoplastic left ventricle), these triplet pregnancies resulted in a stillbirth rate of 2.2% (13:584), a neonatal death rate of 2.8% (16:571), and a corrected perinatal mortality rate of 5% (29:584). There was no significant difference in the neonatal death rate when birth order was considered [Triplet A, 5:192 (2.6%); Triplet B, 6:192 (3.1%); Triplet C, 8:191 (4.2%)].

Comment

The recent suggestion that triplet gestations may be candidates for selective first-trimester reduction crystalizes the importance of reassessment of the perinatal risk associated with these gestations.[11] The ethical justification for this recommendation is based on an assessment of the proportional risks encountered by either continuation of the triplet gestation or by selective reduction to a singleton or twin gestation. It is imperative that up-to-date information be available on which to base such risk versus benefit analyses.

The available recent literature on the outcome of triplet gestations indicates a perintal mortality rate that ranges from 13.3% to 33%.[1-4, 6, 8-10] The applicability of these reviews is limited either by their small size or by the prolonged period of time required to accumulate sufficient cases. The current review is unique not only because of its large size but also because these triplets were managed during a contemporary time frame. The corrected perintal mortality rate of 5% in this review represents a threefold to sevenfold improvement on previously reported series.

It is important to realize that this review does not represent an intensive management protocol at a single university center, but rather the accumulated experience of literally hundreds of obstetricians in the United States. This excellent perinatal survival rate (95%) reflects the general improvement in obstetric and neonatal care that is available throughout the country to women with all manner of obstetric complications.

Another unique aspect of this review was the goal of

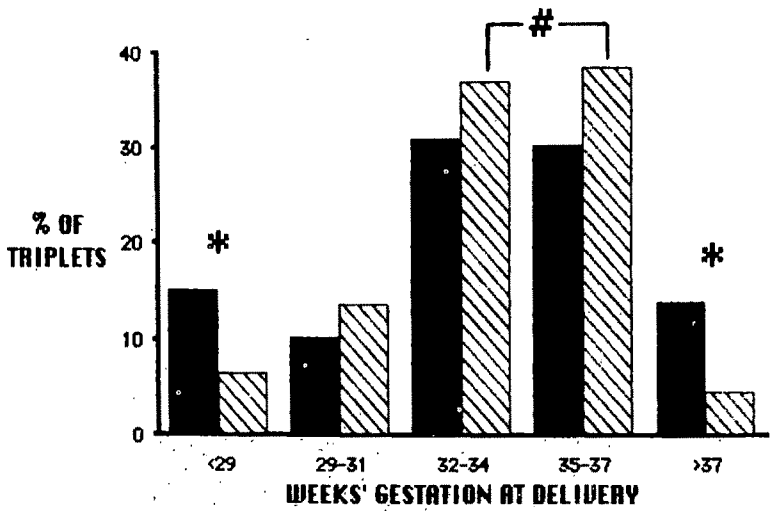

Fig. 3. Gestational age distribution at delivery of 198 triplets in current review *(striped bars)* and compilation of 159 triplets reported in previous reviews[1-3, 8-10] *(black bars)*. *Represents significant increase in deliveries at these gestational ages compared with current series ($p \leq 0.01$). #Represents significant increase in deliveries between 32 and 37 weeks' gestation compared with previous reviews ($p \leq 0.01$).

provision of antepartum care for the triplet pregnancy on an outpatient basis. Hospitalized bed rest was ineffective in the prolongation of gestation or the improvement of outcome for twin pregnancies in two prospective and randomized trials.[12, 13] However, the frequently stated recommendation for triplet pregnancies remains hospitalized bed rest in the third trimester.[1-5] In the triplet series reported by Ron-el et al.[2] and Berg et al.,[5] the average duration of hospitalization for each triplet pregnancy was approximately 40 days.

Despite a desire to provide outpatient triplet management, 44% of the triplets required admission on one or more occasions not including admissions because of preterm labor. Each of these 88 women was hospitalized for an average of 15 days. Despite this very high antepartum admission rate, the overall savings in terms of hospital days by the avoidance of routine hospitalization is remarkable. If all 198 women in this series had been admitted for an average of 40 days each, the hospital days consumed would have totaled 7920 rather than the 1338 actually required. This represents a savings of 18 years of hospitalization for this one clinical series. Given the excellent perintal survival achieved in this series, it is clear that outpatient management of the triplet gestation is justifiable.

It is tempting to speculate as to what specific factors contributed to the improved outcome reported in this series. Certainly the contemporary benefits of early diagnosis, improved ultrasonic visualization, antepartum surveillance, therapy with tocolytic agents, in utero fetal therapy, and dramatic improvements in the neonatal care of the very-low-birth-weight infant have all contributed independently. However, the particulars of this review do raise some interesting points for discussion.

This review demonstrates that the use of prophylactic tocolysis with triplet gestations is very popular among obstetricians in the United States. However, the effectiveness of prophylactic tocolysis remains a very controversial issue, at least as it pertains to the management of the twin gestation.[14-16] Ron-el reported no differences in the average length of triplet gestation between six women without prophylactic tocolysis and eight women who received β-adrenergic agents prophylactically. Eleven other triplets who received a combination of oral β-adrenergic agents and intramuscular progesterone prophylactically actually had gestation shortened by almost 2 weeks.[2] In this particular series, we also found that use of prophylactic tocolysis was not associated with any obvious improvement in either gestational age or birth weight at the time of delivery. These findings may be biased if practitioners were more likely to use prophylactic tocolysis in cases they perceived to be at the greatest risk. This selection bias probably explains the poorer obstetric performance of women who underwent cervical cerclage.

The involvement of ambulatory perinatal nursing in the outpatient surveillance of the triplet gestation represents a significant new trend in the management of these pregnancies. Daily ambulatory nursing contact and uterine activity monitoring represents an intensive antepartum surveillance effort. This effort is directed at making the earliest possible diagnosis of preterm labor, thereby allowing the more effective use of tocolysis.[17, 18] It is controversial as to whether daily uterine activity monitoring is additive to the value of frequent

personal contact and reinforcement of the principles of good prenatal care offered by the perinatal nursing team.[19] That question cannot be addressed by the current review as both elements were emphasized in the antepartum surveillance of these women.

Despite the very high incidence of preterm labor in all reported series of triplet gestations, the use of tocolytic therapy is only rarely described. Itzkowic[9] attempted tocolysis in seven of 46 women and was successful in delaying delivery more than 48 hours in three women. Holcberg[3] used tocolysis in five of 23 patients with a >48-hour success in four women. Certainly others have used tocolysis successfully with triplet gestations but no one has reported the frequency of use or the degree of success currently reviewed. Only 29% of the triplets with preterm labor were not candidates for tocolysis and 52% were tocolyzed for >7 days. The mean time gained in utero for those women who received tocolysis was almost 4 weeks.

It was surprising that the mean age and birth weights at delivery in this series were not significantly different from many previous reports without such extensive use of tocolytic agents.[1-3, 8-10] However, comparison of these previous reports with the current review made it apparent that the gestational age distribution at delivery was altered. It is possible that the effect of aggressive surveillance and therapy with tocolytic agents was to prevent very early preterm delivery (<29 weeks), which is associated with the highest rate of perinatal mortality. The reduced frequency of very early deliveries is counterbalanced by fewer deliveries that occurred >37 weeks' gestation and therefore more deliveries that clustered between 32 and 37 weeks' gestation. The reduced number of triplet gestations delivered >37 weeks' gestation may reflect in part the high incidence of elective delivery that occurred both prematurely and once 37 weeks' gestation was achieved. This very high incidence of elective preterm delivery is an interesting finding and deserves further consideration. In some of these cases, elective preterm deliveries were performed after documentation of fetal lung maturity by amniotic fluid phospholipid studies. However, in the majority of these premature deliveries there was no such documentation. Only speculation can be offered for these elective premature deliveries but possibilities include concerns over maternal well-being and pessimism over the likelihood of further prolongation of pregnancy. The frequency of elective delivery in this review underscores the impact that obstetric decision-making can have on the results found in retrospective clinical reviews.

The almost universal use of cesarean delivery is another dramatically changing trend in the management of the triplet gestation. The cesarean section rate ranged from 7% to 32% in the previously mentioned reports,[1-3, 8-10] as opposed to the 94% cesarean section rate in the current series. The impact of the increasing cesarean section rate can be evaluated by consideration of the influence of birth order on perinatal mortality. Even with a smaller number of triplet pregnancies for evaluation, almost all authors have identified an increasing perinatal mortality rate for the second and third triplet.[1-3, 8, 9] These authors suggest a variety of explanations including an increased risk of delivery trauma, intrapartum cord prolapse, placental abruption, and subtle alterations in uteroplacental blood flow that occurs after delivery of the first or second triplet. In the current series the second and third triplet continues to manifest a nonsignificant increase in perinatal mortality; however, the absence of the dramatic differences seen in previous reports suggests that cesarean delivery may improve the prognosis for aftercoming triplets by avoidance of most of these potential intrapartum complications. There was no maternal mortality in this series; however, the dramatic increase in the cesarean section rate must be associated with increased maternal morbidity and longer hospital stays.

This review of the contemporary obstetric management and neonatal outcome of 198 triplet gestations indicates that the outpatient management of the triplet gestation is completely justifiable and is associated with a much better perinatal survival rate than previously reported. Without the benefit of prospective randomized trials it is impossible to clearly define the factors most responsible for this improvement. However, the current series raises the possibility that the routine use of antepartum hospitalization is unnecessary and that prophylactic therapy with tocolytic agents does not significantly contribute to the improved prognosis for triplet gestations. It is believed that intensive antepartum surveillance, aggressive therapy with tocolytic agents, and the liberal use of cesarean section were helpful in providing these women and their neonates the best possible outcome. It is hoped the findings of this series may spur further investigation with a proper randomized study design to assess which characteristics of antepartum care contribute most to successful outcome for the multifetal gestation.

Discussion

DR. ALLAN G. W. MCLEOD, Miami Florida. A series of 198 women with triplets collected over a 3-year period is, without question, of significance. The 63.6% incidence of preterm labor is not unexpected; however, a 5% (29:584) corrected perinatal mortality rate is impressive. Of particular note is the observation that this represents a three-fold to sevenfold improvement over outcomes in previously reported series.

It has been correctly stressed that this is not a single center study, but is one that involved numerous obstetricians in different areas, a fact that makes the perinatal outcome even more impressive.

The emphasis on outpatient care is described as unique. One might question this description in light of the fact that 63.6% of the women had premature labor and 44% required admission on one or more occasions because of other reasons. The authors reported a significant reduction in the number of hospital days compared with an average 40-day stay for routine hospital admissions; however, not all triplet pregnancies are admitted in such a manner. I wonder whether the overall cost savings would be as great as one might initially believe. I agree, however, that they have shown that more emphasis on outpatient management is justifiable. What is not quite so clear is whether it was the daily nursing contact with early prenatal care, daily telephone contact, education, reassurance, and reinforcement, or the uterine activity monitoring, or a combination of the two factors that made the difference. Did the authors have the opportunity to look at the effect of daily nursing contact alone? There is a singular lack of controlled studies in this area. This information is needed before recommendation of wholesale use of uterine activity monitoring. Also, did the use of Tokos Medical Corporation monitoring produce a significant number of unnecessary admissions for "threatened preterm labor," which would have been avoided if palpation and monitoring for cervical changes had been used?

The suggestion that the effect of careful surveillance is reduction of very early preterm labor is an important concept; it is noteworthy that only 6.6% of the mothers were delivered before 29 weeks' gestation.

Reduction of the possible complications of labor and delivery by a 94% cesarean section rate is reported; however, it is important to emphasize the need to have an experienced surgeon and anesthesiologist present, plus adequate pediatric assistance. This report also shows that a trend toward higher perinatal mortality with the second and third twins, which, although not statistically significant, exists even when a cesarean section has been performed. There was no discussion of maternal complications associated with the increased number of cesarean sections; however, I do not disagree with this approach to delivery.

In this series the higher number of white women and the increased incidence of induced or in vitro fertilization (the latter is an expensive procedure), are suggestive of a higher socioeconomic status that reflects improved nutrition and the ability to rest at home and to understand and follow instructions.

Equally important may be the suggestion that early institution and continued use of tocolysis produces significant prolongation of pregnancy, whereas prophylactic use of β-mimetic agents was not associated with any improvement in outcome. Was hydroxyprogesterone caproate (Delalutin, Squibb, Princeton, N.J.) used for prophylaxis by any of the participants?

I concur with the authors that prospective randomized trials are needed to more clearly define the factors most responsible for the improvement in outcome. Nonetheless this general report is a significant one in the attempt to improve outcome for all women with

triplets and I encourage the authors to continue their efforts in this field.

Dr. Lawrence D. Devoe, Augusta, Georgia. I think this is a remarkable tour de force to get this kind of information with this level of detail from so many centers around the country that involve so many different forces. In terms of those of us interested in multifetal gestation, I do not think there are a lot of new take-home messages because those who have studied this issue recognize the uselessness of prophylactic tocolysis and cerclage. I think what the study enables us to uncover, which I think the authors probably can present to us, is the profile of women who do well. This would then allow rational, logical, individualized care, which is what these patients really need rather than protocolized nonthoughtful care that puts all patients in one category or another. I think that would be something that would be very interesting for them to put together and share with us at a later date.

Dr. Walter Morales, Orlando, Florida. I wonder what proportion of these patients were indigent patients and I wonder whether the author would recommend the same approach to the indigent patient? I did not catch how many of these preterm gestations were complicated with stillbirth and what was the outcome of the remaining two infants in the face of a fetal death in utero?

Dr. Gene Burkett, Miami, Florida. As to what Dr. Devoe said, I wonder whether the authors would look a little bit more carefully at the respiratory distress syndrome. We have information from collaborative studies that corticosteroids do not work well for various reasons. They have a unique opportunity with this kind of volume to look not only at the risk factors that may lead to early delivery, but possibly at administration of steroids given a different way than that to which we are accustomed.

Dr. H. B. Perry, Elkin, North Carolina. I would like to emphasize that early diagnosis in any kind of planned management is significant. Would the authors comment with regard to the birth order and interval between deliveries and its effect on anoxia and infant morbidity?

Dr. Herbert Hopwood, Arlington, Virginia. When do they electively decide to deliver these patients? If it is early with a poorly developed lower uterine segment, do they do a vertical or a transverse incision in the uterus?

Dr. Robert Yowell, Durham, North Carolina. I had the privilege of discussing our experience with the use of Tokos Medical Corporation and with our high-risk preterm labors and twin gestations. I would like to ask the authors whether they have had any experience with the terbutaline pump in their patients.

Dr. Newman (Closing). Dr. Yowell, I have not had any experience with the terbutaline infusion pump with a triplet gestation. I have used it with preterm labor in other settings, and I think it is a very exciting modality for long-term therapy with tocolytic agents because of the advantage of low-dose subcutaneous infusion, but I have not used it in triplets.

Dr. Hopwood, the patients who were electively delivered were managed by several different obstetricians. As I reviewed this, I was very impressed with the different gestational ages at which they were electively delivered. Sometimes there seemed to be no rhyme or reason to it. The patients would achieve 35 weeks' gestation and it would be determined it was time to deliver. At other times, the patients were assessed by amniotic fluid phosolipid studies for fetal lung maturity. I think this is a mixed group of patients. I am not sure if all of these elective deliveries are a good thing or a bad thing, but they probably represent a special group of patients who need to be looked at more specifically. As to the type of cesarean sections used, I cannot say. I believe that in most instances the triplet gestation, despite frequently not having had the benefit of labor, will still have a well-developed lower uterine segment. However, you should always expect malpresentation with triplets and I would not be surprised if many people did use vertical incisions to either overcome an undeveloped lower uterine segment or more easily manage malpresention. The effect of delivery intervals is very interesting. It is something that has been discussed at length for twin gestations, particularly when vaginal deliveries were planned. I think the whole focus of that issue has changed with the introduction of continuous monitoring during the entire second stage of labor. I cannot comment on how delivery intervals may affect the triplet gestation because so many of them were delivered by cesarean section. There were three attempts at vaginal delivery that resulted in cesarean section. Two had cord prolapses and one had a placental abruption, all of which happened fairly quickly after delivery of the first infant.

Dr. Burkett raised a very interesting question about respiratory distress syndrome and corticosteroids. This is a very controversial issue and most of the evidence shows that corticosteroids probably are not of much benefit in the multifetal gestation, at least among twins. I believe this is because of acceleration of lung maturity in these infants. The respiratory distress syndrome rate that we had of 23% is not different from what is reported in some older reviews that looked at neonatal morbidity. Therapy with corticosteroids, however, is very popular and was used extensively by obstetricians when confronted with the triplet gestation in preterm labor. Its wide use precludes any meaningful evaluation of its effectiveness. Once again, I think it is a very good point that the ones who had respiratory distress syndrome may be a group of patients to look at with regard to what risk factors they may have had.

Dr. Morales mentioned that this is probably a socioeconomically privileged population. I know there are both indigent and Medicaid patients involved in this series, but the majority are in the middle to upper class socioeconomic strate. However, I wound not change my recommendations for management, even for an indigent care population. Obviously efforts at outpatient management may have to be altered depending on the individual circumstances involved.

The effect of a single stillbirth among three I cannot recall in specific detail. We had several instances in which this did occur. One was a patient who we managed who had a stillbirth ultimately explained by a transfusion syndrome with vascular thrombosis. We hospitalized the patient at that point and she was followed-up another 2 weeks until she spontaneously ruptured her membranes. I do not know of any instances in which a single loss was followed at a later date by another loss.

Dr. Devoe mentioned the excellent data collection, and I must applaud Ms. Cheryl Hamer, who was of incredible assistance in this project. Ms. Hamer is the manager for international research for Tokos Medical Corporation and was responsible for the coordination of the data-collection efforts. Dr. Devoe also raised another excellent point with regard to the profile of those patients who did very well, whether you define that by laboring at term or by birth weight. This is something we will investigate.

Maternal mortality in North Carolina: A forty-year experience

W. Joseph May, MD, and Frank C. Greiss, Jr., MD
Winston-Salem, North Carolina

An analysis of 67 maternal deaths from January 1, 1981, through December 31, 1985, are reported in detail and in the perspective of 3780 maternal deaths previously reviewed in North Carolina since January 1, 1946. Although the direct obstetric mortality rate has decreased 95% over the 40 years, within causal mortality groups the rates have changed variably during the past 5 years. For the first time, no deaths from obstetric infection occurred. Whereas deaths from toxemia continue to decline, those from hemorrhage, embolism, and anesthetic complications remain unchanged. Within the hemorrhage causal group, deaths from ectopic pregnancy have risen to 70%. The maternal death rate after 20 weeks' gestation is almost 10 times that associated with pregnancy interruptions. Of particular concern is the relative risk of death between the nonwhite and white patients. The North Carolina data are reviewed in the light of those in the South Atlantic region and in the nation as a whole. (Am J Obstet Gynecol 1989;161:555-61.)

Key words: Maternal mortality, direct obstetric deaths, abortion-related deaths, relative risks

A Maternal Mortality Committee was constituted by the North Carolina State Medical Society in 1945. During the succeeding 40 years, the records of 3851 maternal deaths have been reviewed and classified. Previous studies have analyzed North Carolina's maternal mortality rates before 1981.[1-4] The present report details deaths during 1981 to 1985 and compares their incidence and cause with those of previous studies. Findings of concern are compared with those of the South Atlantic region* and of the United States as a whole from 1981 to 1985. Despite differences in data collection and reporting, the North Carolina experience appears to reflect that of the South Atlantic region and the United States.

From the Department of Obstetrics and Gynecology, Bowman Gray School of Medicine of Wake Forest University.
Presented at the Fifty-first Annual Meeting of the South Atlantic Association of Obstetricians and Gynecologists, Hot Springs, Virginia, January 29–February 1, 1989.

Material and methods

The records of 71 deaths that occurred from January 1, 1981, through December 31, 1985, were reviewed and analyzed. With the cooperation of the North Carolina State Health Department, birth certificates were cross-checked with death certificates to assure completeness of the data collection. The classification of obstetric causes of death recommended by the Committee on Maternal and Child Care of the council on Medical Service, American Medical Association,[5] was used. This classification defines a maternal death as "the death of any woman dying of any cause whatsoever while pregnant or within 90 days of the termination of the pregnancy, irrespective of the duration of the pregnancy at the time of termination or the method by which it was terminated." A direct obstetric death is a death that results from complications of the pregnancy itself, from intervention elected or required by the pregnancy, or from the chain of events initiated by the complications or the intervention. An indirect obstetric

death is a death that results from disease that existed before or developed during pregnancy (not a direct effect of the pregnancy) that was obviously aggravated by the physiologic effects of the pregnancy and caused the death.

Autopsy confirmation of the cause of death was obtained in 88% of cases.

Of the 71 deaths, 67 met the criteria for a maternal death, 56 of which were from direct and indirect causes. Since the advent of elective abortions, our maternal mortality rates have been expressed as a function of the sum of reported live births plus elective abortions. This permits realistic comparisons with earlier data. For comparison with regional and United States data, North Carolina maternal mortality rates were expressed as a function of live births alone.

Results

During the 5-year study period (1981 to 1985), 428,891 live births and 155,498 elective abortions occurred. A total of 54 direct and indirect maternal deaths were unrelated to elective abortion (12.6:100,000 live births) and two deaths succeeded one elective and one indicated abortion (1.3:100,000 abortions). The distribution of maternal deaths by classification is shown in Table I and compared with prior experience in Fig. 1. Over the 40-year period, maternal deaths from obstetric causes have decreased 95%.

Specific causes of the direct obstetric deaths are presented in Table II and compared with prior experience in Fig. 2. For the first time, no deaths primarily attributable to obstetric infection ccurred. Similar to the experience since 1965, toxemia, embolism, and hemorrhage were the leading causes of maternal deaths with anesthestic complications a distant fourth but consistent cause. In contradistinction with deaths from toxemia that have maintained a steady decline during the study period, death rates from embolism, hemorrhage, and anesthetic complications were essentially unchanged from the 1976 to 1980 period. It is significant that deaths from ectopic pregnancy accounted for an increasingly larger proportion of all deaths from hemorrhage, rising from 16% in 1975 to 33% in the 1976 to 1980 period and to 70% in the current period. The four deaths attributed to anesthetic complications were all associated with difficult endotracheal intubations during induction of anesthesia for cesarean section, and three women were markedly obese.

Two deaths were possibly of iatrogenic origin. One patient was hypotensive from profuse bleeding and an attempted right subclavian venocentesis resulted in an arterial perforation, hemopericardium, and death. In the second patient, tocolysis to control premature labor was complicated by congestive heart failure with subsequent death from adult respiratory distress syndrome.

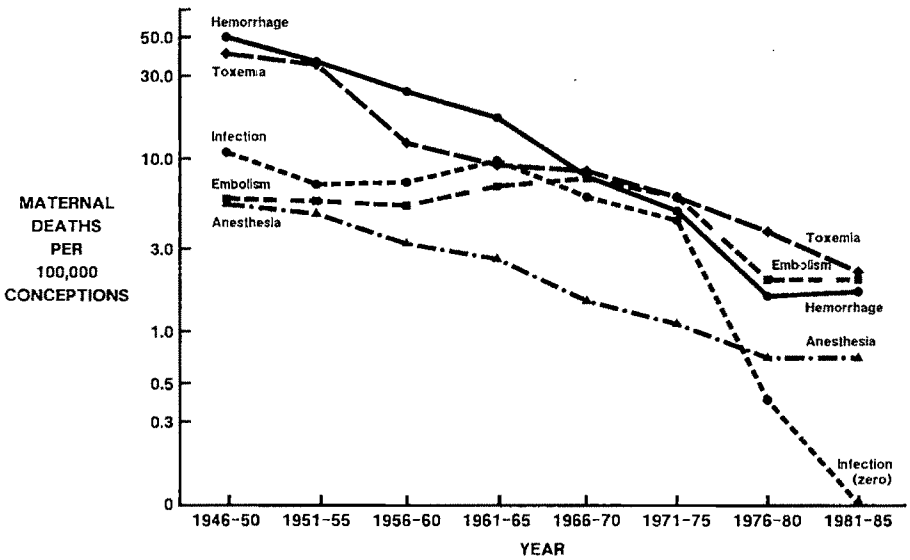

Fig. 2. Semilogarithmic graph of major direct obstetric death rates by cause in North Carolina from 1946 to 1985 by 5-year cohorts.

Specific causes of indirect obstetric deaths are presented in Table III. As in previous reviews, cardiac disease and nonobstetric infections accounted for the majority of deaths.

Two deaths complicated interruption of pregnancy. One patient with coronary artery disease died of a myocardial infarction. The second patient merits special attention. Two weeks after an "elective first-trimester abortion" she had abdominal pain and a low-grade fever and was treated by a second physician because of pelvic infection. She died 10 hours later, and autopsy confirmed a ruptured ectopic pregnancy. It is not known whether products of conception were positively identified at the time of the abortion. Delayed diagnosis as a factor in 67% of 24 deaths caused by ectopic pregnancy has been previously reported.[6]

Although the reduction in the nonwhite (primarily black) maternal mortality rates have paralleled those of the white race in North Carolina during the past 20 years (Fig. 3), the relative risk of death among nonwhite women compared with white women was relatively constant from 1966 to 1980 at 2.6% and 2.7%, respectively. However, during the 1981 to 1985 period, that relative risk rate rose to 3.3%. In an effort to more closely define the sources of these differences, relative risk rates were developed for causal categories of maternal deaths (Table IV). It is clear that the relative risk rate of direct obstetric deaths primarily accounts for the difference; toxemic and hemorrhagic deaths are quite disparate from the other causes at 11.1% and 4.8%, respectively.

Comment

State and national maternal deaths are variously discovered and described statistically. In North Carolina, correlation of birth and death certificates has been used to discover pregnancy-related deaths. We believe this to be the most accurate method and our opinion is confirmed by individual state and national statistics. Demographic data taken from state Health Department vital statistics have been found to be notoriously deficient. In a previous study, eight collaborators who

worked in cooperation with the American College of Obstetricians and Gynecolgoists (ACOG) and the Centers for Disease for Control (CDC) found 37% more deaths than were uncovered through current "normal" CDC channels.[7] Currently the CDC is devising a new reporting system that will be implemented uniformly throughout the country. We expect this will result in more accurate reporting. One problem may be a need for redefinition of maternal death.[8] Medical progress now permits sustentation of life well beyond the 90 days originally defined by the American Medical Association. Clearly, a system that accounts for such new achievements must be developed. In addition, a standard approach to the separation of elective abortion-related deaths from traditional maternal deaths must be used. The concept of reproductive-related deaths adds the additional obfuscating factor of contraceptive-related deaths and this also must be standardized.

Although there has been a progressive decline in pregnancy-related deaths in North Carolina during the past 40 years, within the direct obstetric causal groups varying trends have characterized the 1981 to 1985 data. As previously noted, deaths from obstetric infection have fallen precipitously since the 1971 to 1975 period and no such deaths occurred during the current report period. We believe this is a result of two main factors: the development of increasingly effective antibiotics and the legalization of elective abortion. Since 1972, no death has occurred in North Carolina from septic abortion. Deaths from toxemia of pregnancy have continued to decline at an almost unchanged rate during the past 15 years. During the past 5 years we have been unable to identify any unique characteristics in this group other than race. Lack of prenatal care was not clearly evident as a major factor in these deaths.

In contradistinction with death rates from infection and toxemia, those from embolism, hemorrhage, and anesthetic complications have remained constant from 1976 to 1980 through 1981 to 1985. Since 1970, deaths from blood clot emboli have decreased 60%, whereas those from amniotic fluid emboli show no trend in either direction. Perhaps we are approaching the irreducible minimum in this area.

As in the South Atlantic region and in the United States overall, deaths in North Carolina from ruptured ectopic pregnancies now comprise 50% or more of all deaths from hemorrhage. Review of the North Carolina experience indicates no significant change in the absolute number of patients who died from ectopic pregnancy since 1970. Therefore, reductions in the number of deaths from other causes of hemorrhage have occurred. For example, were we to delete the deaths from ectopic pregnancy from the current North Carolina data, the remaining death rate from hemorrhage would be the lowest of the direct causal groups (0.51 : 100,000 conceptions). One death

from ectopic pregnancy was preceded by an elective abortion. Although an ectopic and an extrauterine pregnancy may coexist, this rarely occurs. It is critically important after an elective abortion to positively identify products of conception. State laws vary on how this should be done. However, should there be any question after careful gross inspection, microscopic confirmation should be mandatory.

Deaths from anesthetic complications represent the most clearly identifiable area for prevention. Consistently these deaths result from aspiration of gastric contents or inadequate ventilation that complicate difficult endotracheal intubations in obese patients about to have a cesarean section. Such circumstances demand the best anesthesia expertise available.

The increased risk of maternal deaths in nonwhite women noted in the North Carolina data is not new and may possibly be rising. These observations prompted us to look at available data from the South Atlantic region and the United States.[9] Table V presents this data for pregnancy-related deaths and specific causal groups. It is clear that with the exception of deaths from toxemia, the North Carolina experience is typical of regional and national data that indicate at least a threefold to fourfold greater risk of death in nonwhite women. We believe that the unusually high death rate from toxemia in North Carolina reflects more precise reporting. Significant risk variations are present in causal groups that cannot be explained specifically. Perhaps the increased frequency of cardiovascular disease in the black race may be a factor in the high frequency of deaths from toxemia. Similarly, an increased frequency of pelvic inflammatory disease may predispose women to ectopic pregnancy. Irrespective of speculation, the uniformity with which the nonwhite woman remains at greater risk for maternal mortality indicates that improved education, improved access to prenatal and delivery care, and continued research into possible medical underlying factors must still be accomplished for the low socioeconomic populations.

To achieve these ends, physicians must become increasingly aggressive in their efforts to further diminish maternal deaths. That we have continually lowered maternal mortality rates over the past 4 decades indicates that quality assurance is nothing new to obstetrics. True, today's litigious climate promotes little enthusiasm for maternal mortality studies. However, lower mortality rates are attainable and our imperative to maintain medicine's pact with the public has never been greater. This study is not a negative judgment on the significant progress made through the past 50 years, but rather it shows us how far we have come and reminds us of how far we have yet to go. It should be out goal to eliminate the disparity in maternal and fetal deaths between white and nonwhite populations.

Discussion

DR. J. BRUCE TAYLOR, Charlotte, North Carolina (Official Guest). I thank Dr. Joe May in his association with Dr. Frank Greiss for an excellent historical review and update of 40 years of obstetric mortality data from the State of North Carolina that encompasses 3851 maternal deaths. His information, presented previously, continues to provide physicians of North Carolina and elsewhere a timely update of this most catastrophic complication of our specialty. Each of these 3851 maternal deaths has undergone an extensive chart review with autopsy verification and interviews, if necessary, to elicit exact information to thereby allow discernment over those complications that are indeed preventable. A review of this information certainly provides us with the historical perspective to know we are doing far better with management of pregnancy than ever before, but there are some alarming trends on the horizon.

As you can see, Dr. May's graphic illustrations (Figs. 1, 2, and 3) show a significant (95%) decrease in the maternal mortality rate (1940, 376:100,000 live births[1]; 1980, 9:100,000 live births[2]; 1985;7.8:100,000 live births[3]). However, I seriously doubt that the objective called for in 1980 of a maternal mortality rate of 5:100,000 live births by 1990 will be attained.[4] The categorization of these obstetric nightmares summarized in Fig. 2 reflect that downward trend with a few highlights herein reiterated.

1. We may very well have reached an irreducible minimum in anesthetic-related deaths with more complications occurring now from morbid obesity than from the gravid state. (Three of four deaths were noted in markedly obese patients.)

2. The perpetual triad of toxemia, embolism, and hemorrhage continues to show essentially an unchanged status from previous data except in the alarming increase in incidence of deaths from ectopic pregnancy.

In review of an article published in December 1987,[5] the death rate from ectopic pregnancy has shown an impressive sevenfold decline (35.2 to 5.3 deaths per 10,000 cases) in the period from 1970 to 1983. During that same time, however, the number of ectopic pregnancies has shown a fourfold increase (17,900 to 69,000). This increased incidence tends to obscure the fact that we are doing a better job of preventing death from ectopic pregnancy. The simultaneous decrease in maternal deaths from other causes (hemorrhage, placenta previa, uterine rupture, infection, and embolism) has resulted in a relative increase in the maternal death rate from ectopic gestation. Unfortunately, the risk of death from ectopic pregnancy is larger for black women (16.1:10,000 cases), other minorities (7.4:10,000 cases), and teenagers (9.5:10,000 cases).[5] Further breakdown of this data reveals that a substantial proportion of fatal ectopic pregnancies occurred in women before they sought obstetric care in our health care system. Consequently, a significant number of these deaths may be preventable. Perhaps the political football being passed about in Congress with regard to maternal care for all women, regardless of economic status, may provide some means to make a distinct improvement in the death rate from ectopic pregnancy.

3. The most impressive category for highlight in Dr. May's statistics is the absence of a maternal death from an infectious source in his most recently collected data. The advancement in antibiotic therapy and life support systems technology has progressed remarkably in the past 10 years, making this an impressive statistic.

However, the most significant infectious disease epidemic in our medical careers, that of acquired immunodeficiency syndrome (AIDS), has come home. Until recently the AIDS problem has been distinctly absent from this, the ultimate heterosexual population, the gravid woman. A total of 20 cases of AIDS-related maternal deaths have been reported (unpublished data)

to augment the six previously reported cases. Although not yet a "problem" in North Carolina, we all will face this epidemic in the next few years if reported projections become reality. Unfortunately, the available information continues to implicate these same high-risk categories: minority, bisexual, and intravenous drug abuse patients. The most pertinent observation made to date in this population of pregnant patients with AIDS has been a shorter diagnosis-to-death interval (113 days versus 187 days for pregnant versus nonpregnant women with AIDS).[6] Whether pregnancy will have an adverse effect on AIDS will only be discernable by further epidemiologic analysis as this crisis unfolds.

4. Dr. May's most astute analysis of these 67 maternal deaths discerned two that were considered to be of iatrogenic origin. This 3% of maternal deaths is prime material for that segment of the legal profession that seeks fast remuneration. Unfortunately, these deaths are a significant inhibition to an effective, nationwide reporting system of maternal deaths. I commend Dr. May in his most diligent efforts of correlation of birth and death certificates to discover pregnancy-related deaths. I fully expect that these two deaths were only discerned by his analysis of this data. Fortunately, the CDC has now devised a new reporting system through the National Center for Health Statistics that it is hoped will eliminate this particular problem and will allow unbiased reporting without fear of potential medicolegal inquiry.

In conclusion, I agree with Dr. May's assessment that we have come a long way since 1946 to improve our care of the gravid patient, but there is more attainable progress, unless AIDS becomes a"bubonic plague" for us as well as for ensuing generations. I commend Dr. May in his association with Dr. Greiss for their diligent efforts in this most unglamorous and, at times, frustrating collection of information. My hope is to see us attain the irreducible minimum in all obstetric complications but, most importantly, in maternal death.

DR. STEPHEN ANDERSON, Winston-Salem, North Carolina. Dr. May, I want to congratulate you and also observe that it is a lot easier to review 5 years of maternal death than it used to be. I sat thinking about the dramatic reduction in deaths from infection and would merely comment that I think most of this is probably related to legalized abortion. At this time it is not particularly popular to speak for medically available abortion, but I think that is probably the case. It behooves all of us to think about that in view of the decisions that are before the Supreme Court. There were dramatic improvements in antibiotic therapy before 1970 that did not have an impact on infection-related deaths as has occurred in the past 10 years.

DR. MAY (Closing). I wish to express my appreciation to Dr. Anderson for making his strong, positive observation on the decline of "infection deaths" as related to the advent of legalized abortion. I hope that Dr. Pearse will transmit this observation through ACOG to our representatives in Washington, D.C. I will provide him with Fig. 2, which supports the contention that medically performed abortion is much safer than is criminal abortion.

I thank Dr. Taylor for his salient observations, especially with respect to the AIDS plague in pregnant women. Possibly, even more remote unrealized causes of maternal deaths may loom over the horizon. This gives us a *raison d'être* for maternal mortality reporting. An irreducible minimum number for specific causes of maternal death is frequently mentioned. Any irreducible minimum number above zero as a cut-off point for maternal mortality study is unacceptable.

The ACOG has provided program time during the past four to five annual meetings for a group of obstetricians who are interested in maternal mortality study. This program has led to a meaningful collaboration between the ACOG group and the CDC. The collaborative efforts have made tremendous progress in the formulation of a uniform maternal mortality report system.

Maternal mortality study and reporting are less than exciting, but like all epidemiology, they are necessary to more precisely know where our attention must be directed to prevent the occurence. I solicit the help of all obstetricians throughout the United States and its territories to participate in the maternal mortality report system through the CDC.

Risk factors for intraamniotic infection: A prospective epidemiologic study

David E. Soper, MD, C. Glen Mayhall, MD, and Harry P. Dalton, PhD
Richmond, Virginia

To determine the cumulative incidence of intraamniotic infection in our hospital and to identify potential risk factors for infection, 408 consecutive patients were followed up prospectively to determine development of intraamniotic infection. The clinical diagnosis of intraamniotic infection was made in 43 (10.5%) patients. Patients with intraamniotic infection were younger, of lower gravidity and parity, more likely to require oxytocin augmentation, and more likely to be monitored internally than were patients who were not infected. They also had longer durations of labor, ruptured membranes, and hospitalization before delivery, had significantly more vaginal examinations, and were more likely to be delivered of infants by cesarean section, as compared with patients without infection. Logistic regression analysis identified four variables independently associated with intraamniotic infection: the number of vaginal examinations, duration of ruptured membranes, use of internal monitors, and duration of total labor. Further study is necessary to clarify the role of these risk factors in the pathogenesis of intraamniotic infection so that infection control strategies can be developed. (Am J Obstet Gynecol 1989;161:562-8.)

Key words: Intraamniotic infection, vaginal examinations, ruptured membranes, internal monitors, length of labor

It has been reported that chorioamnionitis or intraamniotic infection develops in between 0.7% and 1.3% of women who are in labor or who have ruptured amniotic membranes.[1-4] This rate of intraamniotic infection is based on retrospective reviews. In addition, potential risk factors that may predispose patients to the development of intraamniotic infection have not been prospectively studied. Our labor suite nurses perceived a high rate of infection in our patient population and a retrospective review of patient records revealed a higher than expected rate of intraamniotic infection. This prompted us to carry out a prospective study to determine the incidence of intraamniotic infection in our hospital. Because we suspected that the increased rate of intraamniotic infection may be related to iatrogenic factors, additional data were collected to identify risk factors associated with intraamniotic infection.

Material and methods

From January 15 to February 22, 1987, 408 consecutive patients admitted to the Medical College of Virginia's Labor and Delivery Suite were followed up prospectively to determine development of intraamniotic infection. The population is indigent and predominantly black.

Definition of intraamniotic infection. The diagnosis of intraamniotic infection was based on the following criteria. The patient had to have ruptured membranes and a temperature >100° F on two occasions at least 1 hour apart or a single temperature >101° F. In addition, the patient had to have one of the following clinical findings: (1) maternal tachycardia (>100 beats/min), (2) fetal tachycardia (>160 beats/min), (3) maternal leukocytosis (>11000/mm^3), or (4) foul-smelling amniotic fluid. Other sources of intrapartum fever such as urinary tract infection, community-acquired respiratory tract infection, intravenous catheter-associated infection, and substantial dehydration were excluded. After the criteria for the diagnosis of intraamniotic infection were fulfilled, patients were started on parenteral ampicillin and gentamicin. These antibiotics were continued during labor and in the postpartum period until the patient was afebrile for 24 hours.

Epidemiologic data. The following data were collected from each patient's record: age, race, gravidity, parity, estimated gestational age, and date and time admitted and delivered of infants. Data were collected on the use of internal monitors, induction of labor, oxytocin augmentation, use of intrapartum antibiotics, route of delivery, duration of ruptured membranes, number of vaginal examinations, and duration of the latent and active phases of labor. The duration of internal monitoring was recorded only for

patients with the clinical diagnosis of intraamniotic infection.

Laboratory data. A complete blood count and two pretreatment blood cultures were obtained for all patients who met the criteria for the clinical diagnosis of intraamniotic infection. A catheterized urine specimen was obtained for culture. An attempt was made to aspirate amniotic fluid from the intrauterine catheter for culture.

Microbiologic techniques. Blood was cultured by the injection of 10 ml of blood into a diphasic medium that consisted of trypticase soy agar as the solid phase and 90 ml of brain heart infusion broth with 0.2% agar as the liquid phase. With a calibrated loop, urine was inoculated onto trypticase soy agar with 5% sheep blood (blood agar) and eosin methylene blue agar. Amniotic fluid was inoculated onto blood agar and chocolate agar for aerobic microorganisms and onto prereduced anaerobically sterilized peptone—yeast extract—glucose media, blood agar, and chocolate agar for anaerobic microorganisms. All media were incubated at 35° C under aerobic and anaerobic atmospheres. Several specimens were cultured for genital mycoplasmas by inoculation onto Mycotrim diphasic media (Hana Biologicals, Inc., Berkeley, Calif.) that was incubated 7 days. All organisms were identifed with standard methods as previously outlined.[5]

Statistical analysis. Discrete data were tested for significance with the χ^2 test or Fisher's exact test. Continuous data were tested for significance with a two-tailed Student's t test. Logistic regression analysis was performed with the diagnosis of intraamniotic infection as the dependent variable. All p values were based on two-tailed tests with $p < 0.05$ considered to be significant.

Results

During the study period, 45 (11.3%) of 408 patients had fever during labor. One patient had a positive urine culture that yielded >1 million colonies per milliliter of *Proteus mirabilis* and she was treated for pyelonephritis. One patient had signs and symptoms compatible with an upper respiratory tract infection and was observed but was not treated. The clinical diagnosis of intraamniotic infection was made in the remaining 43 (10.5%) patients. Urine cultures were negative in all but one of the patients who had intraamniotic infection. *P. mirabilis* and enterococci were recovered from her urine, but an amniotic fluid culture was positive for >1 million colonies per milliliter of *Escherichia coli.*

All patients with intraamniotic infection were febrile and had ruptured membranes. The mean temperature for infected patients was 101.5 ± 0.8° F, compared with 99.0 ± 0.7° F for uninfected patients ($p \leq 0.0001$). The mean white blood cell count was 14,617 ± 4907/mm³ in patients with intraamniotic infection and 11,877 ± 3737/mm³ in the uninfected patients ($p = 0.0026$). Most patients (34/43, 79.1%) met at least four criteria for the diagnosis of intraamniotic infection. All patients with leukocytosis as the only additional criterion for the diagnosis of intraamniotic infection had a white blood cell count >15,700/mm³.

Table I. Demographic data

Characteristic	*Intraamniotic infection (n = 43)*	*No intraamniotic infection (n = 365)*	*p*
Age* (yr)	21.3 ± 3.3	23.3 ± 5.5	0.002
Race, n (%)			
Black	30 (69.8)	211 (57.8)	
White	13 (30.2)	148 (40.6)	
Other	0 (0)	6 (1.6)	NS
Gravidity*	1.9 ± 1.1	2.4 ± 1.6	0.04
Parity*	0.4 ± 0.6	0.9 ± 1.3	0.005
Estimated gestational age (wk)	39.0 ± 2.5	38.5 ± 4.5	NS

*Data expressed as mean ± SD.

Demographic data are presented in Table I. Patients with intraamniotic infection were younger and had lower gravidity and parity than did patients who were not infected. A total of 67% (29/43) of patients with intraamniotic infection were nulliparous, compared with 43.6% (159/365) of the uninfected patients ($p = 0.002$). Premature delivery (<38 weeks' estimated gestational age) occurred in 18.6% (8/43) of patients with intraamniotic infection, and 11.6% (5/43) of the infants weighed <2500 gm. This was not significantly different from the rate of premature delivery (24.9%, 91/365) in uninfected patients.

Patients with intraamniotic infection were more likely to require oxytocin augmentation and to be internally monitored. Infected patients also had longer durations of labor and ruptured membranes and had significantly more vaginal examinations when compared with patients without infection. Infected patients were also more likely to be delivered of infants by cesarean section, primarily because of failure to progress in labor, than were patients without intraamniotic infection. These data are summarized in Table II.

Patients with intraamniotic infection demonstrated a longer duration of hospitalization before delivery (59.2 ± 119.1 hours) when compared with patients without intraamniotic infection (24.3 ± 85.4 hours, $p = 0.02$). We noted that 25.3% (16/63) of patients with admission-to-delivery intervals >24 hours became infected, compared with 7.8% (27/345) with intervals <24 hours ($p = 0.002$).

Logistic regression analysis identified five variables independently associated with the diagnosis of intraamniotic infection (Table III). When the outcome variable cesarean section was eliminated from the model, inter-

Internal monitors	3.652	1.698	5.77	0.016	0.117
Cesarean section	1.813	1.519	17.38	0.001	0.237
Total labor	0.089	0.434	13.46	0.001	0.205
Vaginal examinations	0.231	0.107	4.66	0.031	0.099
Duration of ruptured membranes	0.016	0.008	3.89	0.049	0.083

nal monitoring, duration of ruptured membranes, number of vaginal examinations, and total duration of labor remained significantly associated with intraamniotic infection (Table IV).

An amniotic fluid specimen was obtained for culture by aspiration of the intrauterine pressure catheter in 18 (41.9%) of 43 patients. All but one yielded at least one microorganism on culture. Aerobic gram-positive cocci were the bacteria most frequently isolated. Group B streptococci were cultured in five cases. Nine of 18 (50%) patients had more than one organism isolated from their amniotic fluid. Five patients had anaerobic microorganisms (*Peptostreptococcus,* 3; *Fusobacterium symbiosum*; and *Bacteroides fragilis*) isolated, and all five had concomitant isolation of aerobic organisms (Table V). One maternal blood culture yielded diphtheroids. This patient also had diphtheroids isolated from the amniotic fluid.

Comment

Determination of the cumulative incidence of clinical intraamniotic fluid infection with prospective patient surveillance has not been previously reported. The intraamniotic infection rate of 10.5% in our patients was considerably higher than the previous estimates based on retrospective record reviews.[1-4] There may be several reasons for this difference. First, data generated by retrospective study may significantly underestimate the true cumulative incidence of intraamniotic infection. Second, our definition of intraamniotic infection was somewhat different from those used in the retrospective studies; only one of those studies used criteria more stringent than ours. Third, the populations studied were also different. Our population was predominantly indigent and black, whereas the populations in the other studies were predominantly Hispanic or undefined.

We observed that the durations of rupture of the membranes and of labor, nulliparity, and oxytocin augmentation were significantly associated with intraamniotic infection. In a retrospective study, Ferguson and associates[3] observed a significant relationship between duration of ruptured membranes and intraamniotic infection. Gibbs and coworkers[6] observed that durations of labor and ruptured membranes were significantly associated with intraamniotic infection in a study of genital mycoplasmas, but it was not stated whether that study was prospective or retrospective.

Use of internal monitors was significantly associated with intraamniotic infection. Two studies[6,7] have previously examined the association between intraamniotic infection and duration of internal monitoring. In the most recent of these two studies,[7] internal monitoring was independently associated with the development of intraamniotic infection. In our series, all patients who had intraamniotic infection with ruptured membranes for <24 hours were internally monitored. These monitors were in place for an average of 12 hours before

Table IV. Results of logistic regression analysis with cesarean section deleted

Variable	*β*	*SEM*	χ^2	*p*	*R*
Vaginal examinations	0.324	0.100	10.42	0.0012	0.175
Duration of ruptured membranes	0.020	0.008	6.12	0.0134	0.123
Internal monitors	3.550	1.601	4.92	0.0265	0.103
Total labor	0.101	0.023	18.87	0.0001	0.248

the clinical diagnosis of intraamniotic infection. Logistic regression analysis confirmed an independent association of internal monitoring with intraamniotic infection.

The number of vaginal examinations was also significantly associated with intraamniotic infection by both univariate and multivariate statistical analysis. Data on the impact of the number of vaginal examinations on postpartum infection are in conflict.[8-10] Our data indicate that internal monitoring and the number of vaginal examinations are important contributors to the occurrence of intraamniotic infection during labor. This relationship with internal monitoring and number of vaginal examinations is strengthened by the results of multivariate analysis that allowed us to control for the duration of ruptured membranes and the total duration of labor. Table VI shows the cumulative probability of the occurrence of intraamniotic infection in monitored patients as the number of vaginal examinations and the durations of ruptured membranes and total labor increases.

The disproportionate number of patients with intraamniotic infection admitted to the hospital >24 hours before delivery also suggests a nosocomial source of these infections. Most of these patients were admitted with either premature rupture of the membranes or pregnancy-induced hypertension. Although the duration of hospitalization before delivery did not emerge from the logistic regression model as a risk factor independent of all of the other variables, further study of this variable is warranted because duration of hospitalization before surgery is a risk factor of postoperative wound infection.[11] This may be a result of the increased exposure to hospital flora or to the underlying condition that requires longer hospitalization.

We found cesarean section to be significantly associated with intraamniotic infection by both univariate and multivariate analysis (Tables II and III). However, because cesarean section occurred after infection, it was considered an outcome variable and not a risk factor of infection. Thus, in further analysis to identify risk factors, cesarean section was excluded from the model (Table IV). Although we observed a nearly fourfold increase in the cesarean section rate of patients with intraamniotic infection, other studies conflict with respect to the association of intraamniotic infection with the need for abdominal delivery.[12, 13] It is unclear whether dysfunctional labor leads to intraamniotic infection and cesarean section or whether intraamniotic infection causes dysfunctional labor that leads to abdominal delivery. Further prospective studies are needed to determine the nature of this relationship.

Table V. Bacteria isolated from amniotic fluid (n = 18)

Microorganisms	*Number of isolates*

Fusobacterium symbiosum	1
Genital mycoplasms	
Mycoplasma hominis	1
Ureplasma urealyticum	2
Total isolates	33

Number of patients with >1 isolate = 9 (50%).

The bacterial species isolated from the amniotic fluid specimens of our patients are similar to those reported by others for patients with intraamniotic infection.[13-15] Isolation of these bacterial species is consistent with the currently held theory that intraamniotic infection develops after bacteria normally found in the lower vagina and cervix ascend to the amniotic cavity.[16] Controversy remains with regard to how these organisms gain access to the intrauterine cavity. Amniocentesis performed in patients with and without ruptured membranes has documented ascending spread of microorganisms without the introduction of a foreign body.[13, 17-20] However, fetal scalp electrodes, internal pressure catheters, and vaginal examinations, especially

Table VI. Probability of intraamniotic infection developing in patients monitored internally with increasing numbers of vaginal examinations and increasing duration of rupture of membranes and total labor

Risk factors			
No. of vaginal examinations	*Duration of ruptured membranes (hr)*	*Total labor (hr)*	*Probability*
2	5.25	6.0	0.03
5	12.00	16.0	0.16
6	16.00	21.0	0.32
8	21.75	29.0	0.63
13	88.00	29.0	0.95

when performed repeatedly, may increase the inoculum of potentially pathogenic bacteria in the amniotic cavity and increase the risk of clinical infection. Our data suggest that this is indeed the case.

In summary, we found a surprisingly high rate of intraamniotic infection in our hospital. Although related to the intrinsic risk factors, duration of labor, and ruptured membranes, this high rate also appears to be related to iatrogenic risk factors such as internal fetal monitoring and multiple vaginal examinations. To our knowledge, these parameters have never been examined as possible risk factors of intraamniotic infection in prospective, comparative epidemiologic studies. Further study is necessary to clarify the role of these risk factors in the pathogenesis of intraamniotic infection. Infection control strategies can then be developed in an attempt to decrease our intraamniotic infection rate.

Discussion

Dr. Billy D. Burk, Rome, Georgia (Official Guest). There is confusion in the literature as to the definition of intraamniotic infection and as a result the true incidence is hard to discern. It has been reported to range from 0.5% to 1.75% and up to 10.5% at the Medical College of Virginia. The diagnosis is confirmed when bacteria or their breakdown products are demonstrated in the amniotic fluid. Cultures may be obtained by means of catheters or by amniocentesis guided by ultrasonography. Rapid confirmation of the presence of organisms can be accomplished by gram stains or by gas-liquid chromatography.

Before labor, bacteria are seldom found in the amniotic fluid. Inhibitory factors in cervical mucus, placental membranes, and amniotic fluid prevent entry of bacteria or their replication. When labor begins and the membranes rupture, bacteria ascend from the vagina into the amniotic cavity where they, by numbers or by their virulence, overcome the inhibitory factors and rapidly multiply.

When the bacteria invade the decidua, the membranes, the placenta, and the fluid in quantity, infection and inflammation lead to maternal fever, maternal and fetal tachycardia, maternal leukocytosis, and foul-smelling amniotic fluid.

Dr. Soper has identified and applied statistical analysis to incriminate: (1) the total length of labor, (2) duration of rupture of the membranes, (3) the number of vaginal examinations and, (4) the use of internal monitoring as risk factors for intraamniotic infections.

I believe the true risk factors are the number and virulence of bacteria that are in the vagina and cervix when labor begins. The increasing and decreasing pressure caused by uterine contraction in labor acts as a pump to enhance the ascension of bacteria into the amniotic cavity. Vigorous vaginal examinations and the introduction of intraamniotic pressure catheters and scalp electrodes add to the inoculation of bacteria into the cavity.

Intraamniotic infection becomes symptomatic when 10^3 colony forming units per milliliter of bacteria are present. The virulence or toxin production of the bacteria determine the severity of the infection.

Young nulliparous patients who had long labors, prolonged rupture of the membranes, numerous vaginal examinations, and internal monitoring had a greater incidence of intraamniotic infection. The bacteria recovered by culture confirmed the theory of ascending infection. Patients who had intraamniotic infection were more likely to require augmentation of labor and had a fourfold greater chance of delivery by cesarean section because of failure to progress in labor.

I would like to ask Dr. Soper the following questions: (1) What is the induction and augmentation policy at the Medical College of Virginia? and (2) When the diagnosis of intraamniotic infection was made, were antibiotics begun?

Dr. Gene Burkett, Miami, Florida. I am a little confused by some of the data presented here as to whether infection preceded manipulations or resulted from manipulations. The author uses premature rupture of the membranes as part of his definition. Is not this study really a study of what happens when rupture of the membranes occurs? About 6 to 8 years ago Ledger showed that there is intraamniotic infection before rupture of the membranes. I would ask the author to define this very clearly so that we can appreciate his point.

Dr. J. Terrell Pope, Macon, Georgia. Were the membranes examined pathologically to determine whether there was evidence of infection or inflammation?

Dr. Herbert G. Hopwood, Arlington, Virginia. I wonder whether Dr. Soper may have considered that he might be using the wrong stimulatory agent. Instead of oxytocin, perhaps he might have used prostaglandins.

Dr. Allan G. W. McLeod, Miami, Florida. A few years ago we had a problem with infection and we went back very bascially to some simple techniques. In the process of vaginal examination in labor, we sponged the vulva carefully with Betadine and used careful separation of the labia before the insertion of the examining fingers each time an examination was done. Infection rate dropped dramatically.

Dr. John W. C. Johnson, Gainesville, Florida. I congratulate the authors on a beautifully designed and executed study. We have been interested in premature rupture of the membranes for a few years. One of the cofactors we found associated with increased intraamniotic infection is gestational age, an inverse relationship. Would Dr. Soper comment on that?

Dr. Soper (Closing). Thank you for your comments. The augmentation and induction policies at the Medical College of Virginia were similar to those used across the country; those patients with hypotonic dysfunctional labor were augmented with oxytocin. Indications for induction included patients at term with ruptured membranes who were not in labor, post dates, and pregnancy-induced hypertension. We administered oxytocin, not prostaglandins, for augmentation and induction. When the diagnosis of intraamniotic infection was made, the studies that I mentioned were performed and antibiotics were started. A combination of ampicillin and gentamicin was administered at our institution.

Dr. Burkett commented on infections that either preceded manipulation or caused ruptured membranes. The great majority of patients in this study had no clinical indication of infection on admission. Subclinical intraamniotic infection may have played a role in premature rupture of the membranes and may have predisposed the patient to the development of clinical intraamniotic infection. Our study did not address this issue. It is important, however, to make the distinction between clinical intraamniotic infection, as defined in our study, and histologic chorioamnionitis, which may not be assoicated with intrapartum fever. We believe that clinical intraamniotic infection may be nosocomial in some cases. Patients admitted to the hospital at term with intact membranes who do not have a fever for at least 2 hours after admission but who later have clinical manifestations of infection may be categorized as having a nosocomial intraamniotic infection. Infections that occur after admission may be related to the iatrogenic risk factors reported in this study. In this subset of patients some type of intervention may decrease the rate of intraamniotic infection. We have designed a new prospective study to further investigate potential risk factors for intraamniotic infection. About 60% of our patients with intraamniotic infection appear to have acquired it in the hospital. In our study, patients rarely became infected before they were instrumented. A second category would be those patients with a community-acquired intraamniotic infection. These are patients admitted to the hospital who already meet the criteria for the diagnosis of intraamniotic infection. These patients make up $<10\%$ of our patients with intraamniotic infection. Finally, a third category would encompass the rest of the patients who have intraamniotic infection. The third category includes patients with premature rupture of the membranes or premature delivery who are afebrile at the time of admission. In these cases the relationship between admission and infection is unknown.

In this study, we did not routinely evaluate the placenta pathologically. However, of those placentas examined by our pathologists, 85% of the placentas from patients with intraamniotic infection showed histologic evidence of chorioamnionitis.

In response to Dr. Johnson's question with regard to gestational age, the majority of our patients with intraamniotic infection were at term. We were concerned that patients in preterm labor would have a higher cumulative incidence of intraamniotic infection, but that was not the case. At the Medical College of Virginia the diagnosis of intraamniotic infection is a clinical entity predominantly seen in term pregnancies.

Dr. McLeod commented that he studied the institution of careful aseptic technique while performing vaginal examinations and found that intraamniotic infection rates were decreased. This information would further strengthen our position that iatrogenic factors do play a role in the overall rate of intraamniotic infection. After we have completed our prospective study, we will use the data to develop preventive strategies.

In conclusion, we were the first to look at overall intraamniotic infection rates prospectively. The currently accepted rate of intraamniotic infection may be an underestimate of the true rate. Additional studies in similar institutions need to be performed to determine accurate rates of intraamniotic infection in various obstetric populations.

Short course of antibiotic therapy in treatment of postpartum endomyometritis

Walter J. Morales, MD, PhD, Evan M. Collins, MD, Jeffrey L. Angel, MD, and Robert A. Knuppel, MD, MPH

Orlando, Florida

To evaluate the safety and efficacy of an abbreviated course of antibiotic therapy in postpartum endomyometritis, 109 patients with endomyometritis were randomized to three study groups. All were treated with clindamycin and tobramycin until afebrility and clinical signs of disease were absent. Patients in group I received antibiotics for ≥24 hours, group II received therapy for ≥48 hours, and group III received antibiotic therapy for ≥48 hours that preceded a 7-day course of oral Augmentin. The groups were similar in size and in demographic and clinical parameters. Two patients from each group required a third antibiotic, and no patient required rehospitalization. Group III required more days of antibiotic therapy than did group I, 2.9 versus 2.1 days ($p < 0.01$), and cost $412.00 more per patient. This data strongly suggest that a short course of antibiotic therapy is efficacious and safe and would result in substantial monetary savings. (Am J Obstet Gynecol 1989;161:568-72.)

Key words: Endomyometritis, short-course antibiotic therapy

Postpartum endomyometritis remains the most common infectious complication of the puerperium. Incidence varies depending on the study cited, but ranges from 20% to 38.5% of patients after cesarean section, and 1.2% to 2.5% of patients after vaginal delivery.[1-3] Because of the polymicrobial nature of the infection, a combination antibiotic regimen of clindamycin and an aminoglycoside has been accepted as standard therapy, and its efficacy has been well documented in the literature.[4-6]

Many studies have proposed various antibiotic regimens, but few have focused on the proper duration of therapy. Many advocate the use of intravenous antibiotics for a minimum of 48 hours of afebrility,[7-9] whereas others recommend 7 to 10 days of oral antibiotics on completion of parenteral therapy.[5, 6, 10-12] Recent studies have advocated the use of shorter courses of antibiotic therapy,[13-15] but none has evaluated the efficacy of clindamycin-aminoglycoside in an indigent population in a prospective randomized fashion. To evaluate the safety and efficacy of abbreviated courses of antibiotics, we studied a group of service patients with the diagnosis of postpartum endomyometritis.

Material and methods

The study was conducted at Tampa General Hospital's postpartum unit from July 1987 through April 1988. Patients were enrolled in the study after they were assigned the diagnosis of postpartum endomyometritis. This diagnosis was established on the basis of a combination of clinical and laboratory findings that included the following: (1) febrile morbidity defined as temperature >100.4° F taken twice at least 6 hours apart, or an isolated temperature spike of 101° F that excluded the first day postpartum, (2) uterine tenderness, (3) leukocytosis, and (4) absence of other foci of infection. Patients who had received prophylactic antibiotics were considered eligible for the study. A catheterized urine specimen with culture and sensitivity, a complete blood count with differential, and two sets of blood cultures (in antibiotic removal device bottles if prophylactic antibiotics had been administered) were obtained before initiation of therapy. All antipyretics were removed from the "standard postpartum orders" and were given only at the discretion of the house officer.

The antibiotic regimen consisted of intravenous administration of clindamycin 900 mg every 8 hours and tobramycin 95 to 140 mg loading dose, then adjusted to 80 to 120 mg every 8 hours based on lean body weight. Tobramycin dosages were adjusted based on serum peak and trough levels, which usually were evaluated after the fifth dose. Tobramycin levels were also adjusted on the basis of serum creatinine levels, which were evaluated at the initiation of therapy and every other day therafter until discontinuation of therapy.

Patients were excluded from the study protocol if they had a known allergy to either clindamycin or tobramycin. Other patients excluded were those being treated for any other infectious process, and those who had immunosuppressive disorders. Patients with bacteremia before the initiation of therapy also were excluded from the final data analysis. Eligible patients were randomized to one of the three treatment regimens: (1) clindamycin-tobramycin for 24 hours of afebrility and asymptomatic, (2) clindamycin-tobramycin for 48 hours of afebrility and asymptomatic, (3) clindamycin-tobramycin for 48 hours of afebrility and asymptomatic, plus 7 days of oral Augmentin (Beecham Laboratories, Bristol, Tenn.).

Therapy was considered to have failed in patients with temperature elevations ≥100.4° F 72 hours after initiation of therapy and in those who displayed persistent uterine tenderness. Thus a third antimicrobial agent, usually a broad spectrum penicillin, was added to the antibiotic regimen. Therapy also was considered to have failed in instances in which sequelae of endomyometritis (bacteremia, abscess, septic pelvic thrombophlebitis) developed, and the treatment regimen was adjusted accordingly.

Table I. Conditions that resulted in exclusion

	Group		
	*I**	*II†*	*III‡*
Positive blood culture	3	3	3
Allergic reaction	1	—	—
Urinary tract infection	—	—	2
Failure to adhere to protocol	2	3	2
	6	6	7

*Clindamycin + tobramycin × at least 24 hours of afebrility.

†Clindamycin + tobramycin × 48 hours of afebrility.

‡Clindamycin + tobramycin × 48 hours of afebrility + oral augmentin × 7 days.

Successful therapy was defined as a complete resolution of fever and symptoms at the completion of the specified therapy. If stable, patients were discharged after completion of therapy, and were instructed to monitor their temperatures at home and to call Tampa General Hospital because of temperatures ≥100.4° F or abdominal pain. Patients who underwent cesarean section were examined 2 weeks after discharge, and were evaluated for signs of persistent disease or sequelae.

The charts of patients who underwent vaginal delivery were reviewed for evidence of rehospitalization or emergency room visits. The data were analyzed with the χ^2 test and p value of ≤0.05 was considered statistically significant.

Results

During the period of study, 5317 deliveries were recorded at Tampa General Hospital and, of these, 843 (15.8%) were delivered by cesarean section. Postpartum endomyometritis was diagnosed in 128 (2.4%) of these deliveries with 81 (63%) of these infections diagnosed after cesarean section. A total of 128 patients with the diagnosis of postpartum endomyometritis were randomized to one of the three study groups; 19 of these patients were excluded from the analysis because of a variety of reasons (Table I). Of the remaining 109 patients, 36, 36, and 37 were included in study groups I, II, and III, respectively.

The demographic characteristics of the study groups are summarized in Table II, which demonstrates that no difference among the groups in terms of maternal age, parity, gestational age, length of labor, length of rupture of membranes, number of digital cervical examinations after rupture of membranes, use of fetal scalp electrode, internal pressure catheter, and the frequency of meconium-stained fluid. The groups were also similar in terms of predelivery and postpartum hemoglobin, use of prophylactic antibiotics, type of anesthetic agent, and incidence of cesarean section, as well

as indications for abdominal delivery (Table III). No difference was observed among the groups in terms of time from delivery to diagnosis of endomyometritis, maximum white blood cell count, and maximum temperature (Table IV).

Although there was no difference among the three groups in terms of total postpartum hospital days, patients from group I required statistically significantly fewer days of antibiotic administration than did those from group III, 2.1 versus 2.9 days ($p < 0.01$). Two patients from each group required the addition of a third antibiotic to achieve satisfactory resolution of the infectious process. Thus there was no difference among the three study groups in terms of success of therapy. One patient was readmitted with complaint of abdominal tenderness 2 weeks after discharge from the hospital. She was discharged without antibiotics after 24 hours and did not have further complaint. Finally, with regard to antibiotic and hospital room costs, the average cost of patients from groups II and III was $233.35 and $412.45 higher, respectively, compared with the average cost of patients from group I.

Comment

Postpartum endomyometritis continues to be a major cause of infectious morbidity in the obstetric patient. Careful timing of amniotomy, limited vaginal examinations, and prophylactic antibiotics for cesarean section delivery may help to reduce the incidence and severity of postpartum endomyometritis. A number of antibiotic regimens have been studied with varying degrees of success, but few clinical trials have addressed the proper duration of therapy.

Three recent articles in the literature have advocated the use of shorter courses of antibiotics for postpartum endomyometritis. In 1986, Duff[15] recommended cessation of antibiotics after 24 to 48 hours of afebrility, although there was little in the literature to support such a recommendation. In 1987, Soper et al.,[13] with historic controls, demonstrated a favorable response to abbreviated therapy with clindamycin-gentamicin in a dependent military population. They agreed that the application of such therapy to an indigent population would need further investigation, and the limitations of such a control group are obvious. Cabbad et al.[14] were successful in the treatment of a group of indigent patients with short courses of imipenem. The study is limited by not only the size of the study group (25), but also by the lack of a control group.

The clindamycin-aminoglycoside regimen was chosen for the following reasons. It is the antibiotic regimen that has been tested most extensively, with cure

†Difference between groups I and III by Duncan's multiple range test.

rates quoted as high as 90% to 95%. Of the patients who received this antibiotic regimen, <0.5% had serious complications of endomyometritis.[15] A commonly quoted disadvantage of aminoglycoside therapy is the need to monitor serum peak and trough levels. In our study, 17 of 36 patients in group I completed therapy by 1.7 days of intravenous administration of antibiotics and thus alleviated the need to monitor serum levels. The rapid elimination of aminoglycosides by the obstetric patient makes toxicity an infrequent complication.[16] Furthermore, Duff and associates,[17] and Blanco et al.[18] in separate studies reported successful therapy with aminoglycosides in significant percentages of patients despite "subtherapeutic" serum levels.

One potential weakness in our study should be noted. No endometrial cultures were obtained before therapy to document infection with resistant or high-virulence organisms. Although these cultures may be helpful to test various antibiotic regimens in vitro, their reliability and practicality in the clinical management of patients with postpartum endomyometritis has been disputed.[19]

In this first prospective randomized study that uses short courses of clindamycin-tobramycin for postpartum endomyometritis, data suggest that the abbreviated regimen may be applicable to an indigent population. Patients in group I had shorter hospitalizations and fewer days of intravenous administration of antibiotics than did those in groups II and III. Of more importance, no increase in morbidity was noted in those who received the abbreviated regimen. Data from this study strongly suggest that a short course of antibiotic therapy is both efficacious and safe, and would result in substantial monetary savings to a busy obstetric service.

Discussion

DR. ROBERT BOWDEN, Lynchburg, Virginia. I would like to know the timing of the determination of your leukocyte count inasmuch as you have exertional leukocytosis that may exist for 24 to 48 hours after delivery. The second point is why did you choose the aminoglycoside rather than one of the more straightforward antibiotics in that early period?

DR. GUY BENRUBI, Jacksonville, Florida. I want to thank Dr. Morales for something that sorely needs to be done. Was there any difference between the groups who had endomyometritis after cesarean section and those who had it after normal vaginal delivery, and were they identical in the three groups they were randomized to in terms of total numbers? The other question is, did you determine whether the Augmentin was, in fact, taken by your patients? Augmentin is a very emetogenic type of medication and I wonder how many of those patients did, in fact, take it? Finally, did your patients who underwent cesarean section have their placentas cultured at the time of cesarean section for any particular reason? Do you have any information of what organisms were on the placenta when you were doing the study?

DR. WILLIAM MIXSON, Gables, Florida. I have not done obstetrics in many years, but it seems to me that an old basic concept was neglected here. A lot of times these patients just need drainage. An intrauterine culture was not done and nothing was done to try to improve drainage in these patients.

DR. MORALES (Closing). Leukocytosis is a very minor criterion, and we did not require leukocytosis to be part of the diagnosis. This was obtained at a time of the diagnosis of endometritis. Why the aminoglycoside? We wanted to use what I consider to be the "gold standard" of therapy for endometritis. We now are conducting studies with single agents, but first I wanted to answer the question of duration; thus the use of the most accepted antibiotic regimen—aminoglocoside and clindamycin. In terms of the difference between the patient who had endometritis after vaginal delivery and cesarean section, they were essentially not different on the basis of the various parameters studied. In terms of whether the patients indeed took the Augmentin, I cannot assure you that they did. This is basically an indigent population. However, no patient enrolled in the study groups required readmission or evaluation in the emergency room because of sequelae of postpartum endomyometritis.

At the time of diagnosis of endometritis, we try to get an endometrial scraping, but of course this was not done 100% of the time. I do have the information on the microbiology. We did culture a number of placentas. In terms of the drainage of the uterus with diagnosis of endometritis, I do not have sufficient experience with endometrial cavity drainage to answer this question.

Subsequent fertility in women who undergo cardiac surgery

Wallace C. Nunley, Jr., MD,[a] Lisa A. Kolp, MD,[a] Laura N. Dabinett, MD,[a] James D. Kitchin III, MD,[a] Bruce G. Bateman, MD,[a] and George B. Craddock, Jr., MD[b]
Charlottesville, Virginia

A retrospective review was undertaken on all pediatric and reproductive-aged females who underwent cardiac surgery and required cardiopulmonary bypass from 1958 through 1986. The purpose of this study was to define the fertility of these patients after surgery and to compare their reproductive performance with that in the general population. Analysis was complete for 208 patients. These patients make up the following cardiac surgical categories: septal defect repairs, 92; commissurotomies, 60; valve replacements, 46; tetralogy of Fallot repairs, 6; and coronary artery bypass procedures, 4. Of 208 patients, 68 (32.7%) attempted pregnancy after surgery. Infertility was defined in five women as follows: endometriosis, 3; ovulatory dysfunction, 1; unknown, 1. A total of 64 patients conceived 121 pregnancies with the following outcomes: live births, 98; spontaneous abortion, 9; ectopic pregnancy, 2; therapeutic abortion, 12. Our results suggest that infertility is not an apparent disorder after cardiac surgery and that subsequent pregnancy outcomes are similar to those in the general population. (AM J OBSTET GYNECOL 1989; 161:573-6.)

Key words: Reproductive performance, cardiac surgery, infertility

Women with congenital and acquired heart disease are able to live healthier lives and to have improved reproductive outcomes because of advancements in cardiovascular surgical technique, refinements in prosthetic valve design, and improvements in medical management of cardiac disease throughout pregnancy. Several published reports detail pregnancy management and outcome after cardiac valve replacement surgery[1-5] and other types of cardiac surgery.[6-8] Additional articles, including a review by Bernal and Miralles,[9] contain information on the outcomes of gestations in patients who required cardiac surgery during pregnancy.[10-15]

Information is lacking with regard to infertility as a possible disorder in women who have had cardiac surgery that required extracorporeal circulation. The purpose of this study was to tabulate the reproductive performance of women after cardiac surgery, including those who attempt pregnancy unsuccessfully. If infertility (defined as the couple's perception of difficulty with conception) was identified, the specifics of the problem were defined as completely as possible.

Material and methods

All cardiovascular surgical procedures performed at the University of Virginia Health Sciences Center from 1958 to 1986 were reviewed. A total of 470 pediatric-adolescent girls and reproductive-aged women <40 years of age who underwent cardiac surgery that required extracorporeal circulation were identified. The surgical procedures selected were atrial and ventricular septal defect repairs, valvular commissurotomies, valvular replacements, coronary artery bypass, and tetralogy of Fallot repairs.

To be included in the analysis of this study, the patient must have been 16 years of age by 1988 and must have had a minimum 2-year follow-up if surgery occurred during her reproductive years. Consequently, 95 patients were eliminated secondary to the age restriction and 23 were deleted from analysis because of lack of follow-up. Questionnaires were mailed to 181 patients from whom additional information was required. A total of 37 completed and returned the questionnaires. Therefore, the sample population totaled 208.

Information extracted from hospital records and the questionnaire included the type of surgical procedure, the year of surgery, and reproductive performance before and after surgery. The hospital record information was deemed adequate in 171 patients, and no questionnaire was mailed. Reproductive performance included information with regard to pregnancy attempts before and after surgery and specific outcomes of all known pregnancies. If difficulty with conception after surgery was acknowledged, the specifics of this infertility diagnosis and management were solicited.

Table I. Age distribution of 208 women at time of cardiac surgery

Age (yr)	*No. of patients*
0-9	41
10-14	17
15-19	27
20-24	27
25-29	28
30-34	33
35-39	35

Results

From the original study population of 470 patients, information was judged to be adequate for analysis in 208 patients. The age distribution of these individuals at the time of their cardiac surgery is listed in Table I. Table II details the different cardiac surgeries performed. Approximately 75% of these patients underwent operative procedures to repair septal defects or valves. The mean age of the patients who underwent septal defect repairs and commissurotomies was approximately 10 years less than the mean age of those who underwent valve replacements.

After cardiac surgery, 140 (67.3%) patients never attempted pregnancy; 16 underwent sterilization; and 68 (32.7%) attempted pregnancy. Five (7.3%) patients acknowledged infertility and listed the following causes: endometriosis, 3; ovulatory dysfunction, 1; unknown, 1. One of the three patients with endometriosis had three live births after management of her reproductive disease. Table III lists the outcomes of all known pregnancies after cardiac surgery as well as conceptions per cardiac procedure. There were no maternal deaths.

More conceptions occurred in patients after septal defect repairs than in those who underwent valve replacements. The mean age of the former group was 18.0 years, compared with 30.2 years in the latter group. Table IV details the relationship of conceptions to the cardiac procedure.

Comment

The incidence of cardiac disease in pregnancy is 1% to 4%.[15] Because of improved medical management of the heart disease, many patients are able to be delivered of healthy infants without significant maternal morbidity. However, if maternal condition deteriorates significantly, cardiac surgery that requires extracorporeal circulation can be performed during pregnancy without an increase in mortality different from that in nonpregnant women.[9] Alterations that involve the uteroplacental-fetal unit during this surgical procedure may include decrease in uterine blood flow and fetal bradycardia with or without the onset of uterine contractions.[16]

However, the purpose of this article is not to detail the management of pregnancy in women after cardiac surgery that required extracorporeal circulation. Rather, our intent is to provide information with regard to the reproductive performance of women who have previously undergone various types of cardiac surgical procedures with an emphasis on the incidence of infertility. Certainly with the physiologic changes, such as transient decrease in blood flow and hypothermia, succinctly described by Lake,[17] one might theorize a potential adverse effect on the neuroendocrine axis that could alter ovulatory status. To attempt to define any effect on ovulation would require serial investigations at different intervals after surgery, a task not done in this study. Only one patient with infertility described the need for ovulatory agents.

Because of the nature of retrospective studies, we concede that it may be difficult to ascertain the absolute incidence of infertility in the population examined. The data suggest that infertility, with an incidence of 7.3%, is not an apparent disorder in women who undergo cardiac surgery that requires cardiopulmonary bypass. Mortensen and Ellsworth[18] found in a series of 168 patients in the childbearing age that 11% were "involuntarily sterile" before their cardiovascular surgery, whereas only 3.6% were "involuntarily sterile" postoperatively.

Maternal age may be a factor that could influence the reproductive performance of patients included in this study. Several patients who previously underwent septal defect and tetralogy of Fallot repairs are still in their reproductive years. Conception may not be as important an issue to older patients who had undergone valve replacement surgeries or coronary artery bypass grafting. Furthermore, the type of cardiac surgery may influence conception and embryo development because anticoagulation therapy would be rec-

Coronary artery bypass grafting	4 (100)	0	0	0	0	0	0
TOTAL	140 (67.3)	68 (32.7)	5 (7.3)	98 (89.9%)	99 (8.3%)	2	12

ommended in those patients after valve replacements. The risks of such treatment to both mother and fetus have been reviewed by Ueland.[8] More recently Deviri and colleagues[5] reported more favorable pregnancy outcomes for those patients who had a valve replacement with porcine xenograft prosthesis (instead of a mechanical device) and were not treated with coumarin derivatives.

The significance of the cardiac disease on decisions with regard to fertility is difficult to define in this study. Certainly many patients had improved quality of life after surgery but possibly not to the point of being comfortable with an attempt at pregnancy. Improved quality of life after heart transplantation has resulted in a vaginal delivery of a healthy female infant as reported by Lowenstein and colleagues.[19] Physician advice to the patient with regard to attitude toward conception was not always apparent from chart review or from the questionnaire.

The pregnancy outcomes detailed in Table III indicate that approximately 90% of pregnancies resulted in live births. Our data suggest that infertility is not an apparent disorder in women after cardiac surgery that required extracorporeal circulation. Furthermore, there is not an increase in pregnancy wastage postoperatively in these patients compared with the general population.

We express gratitude to Dr. Stanton Noland, head of cardiovascular surgery at the University of Virginia Health Sciences Center, for permission to review the cardiovascular operative records. Appreciation is given to Ms. Brenda Kennedy for her assistance with the questionnaire.

Table IV. Relationship of conceptions to cardiac operations

Procedure	No. of patients who conceived		
	Before surgery	After surgery	Before and after surgery
Septal defect repairs	19	31	3
Commissurotomies	23	16	5
Valve replacements	27	5	1
Tetralogy of Fallot	0	3	0
Coronary artery bypass grafting	4	0	0

Fertility after ectopic pregnancy

Dorothy E. Mitchell, MD, Helen F. McSwain, MD, and Herbert B. Peterson, MD
Atlanta, Georgia

In the period July 1983 to March 1985, 264 women had surgery for ectopic pregnancy at Grady Memorial Hospital; 76 had postoperative hysterosalpingograms. Of these, 55 (76.4%) women were followed up for 3 to 41 months (mean, 23.8) to determine subsequent fertility. During the follow-up period, 30 pregnancies occurred among the 55 patients; 24 were intrauterine and 6 were repeat ectopic pregnancies. In the surgical group of 39 patients with salpingectomy, 60.8% of those desiring pregnancy achieved an intrauterine pregnancy. Of the 12 patients with salpingostomy, the three who desired pregnancy achieved it (100%). In the tubal abortion group, the two women desiring pregnancy conceived (100%). There were six repeat ectopic pregnancies (10.9%). Of the ectopic pregnancies, one occurred in the salpingectomy group (2.6%), four in the salpingostomy group (33.3%), and one in the tubal abortion group (25%). Five of the six ectopic gestations were found in the contralateral fallopian tube. Hysterosalpingographic evidence of contralateral tubal patency was a good prognostic indicator for subsequent intrauterine pregnancy. By contrast, one half of study patients with findings suggesting tubal occlusion still achieved an intrauterine pregnancy. (Am J Obstet Gynecol 1989;161:576-80.)

Key words: Ectopic pregnancy, postoperative hysterosalpingograms, subsequent fertility

The incidence of ectopic pregnancy has increased dramatically over the past decade, making this condition an increasingly important individual and public health concern. At Grady Memorial Hospital, the ratio of ectopic pregnancies to live births in 1986 was 1:34. To better characterize factors associated with reproductive outcome after ectopic pregnancy in our patient population, we conducted a prospective study of women with surgical management of ectopic pregnancy during the period 1983 to 1985. Previously we reported on the correlation between clinical characteristics of these women and postoperative hysterosalpingography.[1] In this article we detail the reproductive experience of study participants through September 1986. We correlate clinical circumstances, including initial surgical procedure and postoperative hysterosalpingogram, with subsequent fertility.

Material and methods

This study was conducted over two time periods. The first involved the enrollment of all women who underwent tubal operation for an ectopic pregnancy at Grady Memorial Hospital between July 1, 1983, and March 31, 1985. The methods for that portion of this study were described in detail elsewhere.[1] In brief, during the study period 264 women underwent operation for ectopic pregnancy. All women with ectopic pregnancy

Table I. Percentage and length of follow-up of women with ectopic pregnancy by surgical management

	Surgical management		
Follow-up	*Salpingectomy (includes partial salpingectomy)*	*Salpingostomy*	*Tubal abortion*
Total No. of patients	52	13	5
Patients with follow-up	39 (72%)	12 (92%)	4 (80%)
Follow-up time (mo)	25 ± 11.2	21.3 ± 9.2	19.3 ± 11.2

were considered for conservative surgical management. Salpingectomy was performed only if more conservative options were not clinically feasible. For isthmic pregnancies, partial salpingectomy was performed. For ampullary pregnancies, linear salpingostomy was attempted when feasible. Although surgical procedures were performed by various surgeons, all used microsurgical techniques without magnification. Seventy-six (29%) of the 264 women underwent postoperative hysterosalpingography with water-based medium as closely as possible to the sixth postoperative week.

In the second period of the study, the subsequent fertility of the 264 women with ectopic pregnancy was evaluated. After medical record review, all study participants who could be located were interviewed by telephone; no women refused interviews. Follow-up interviews continued until September 1986. Information regarding desire for pregnancy and occurrence of pregnancy was obtained during the interview. When pregnancy was reported, detailed information was obtained when available. In all cases when ectopic pregnancy was reported, the occurrence was verified by review of the medical record. The length of follow-up was established for each individual as the time from the initial surgery for ectopic pregnancy to the time of the telephone interview or the date of the last pertinent entry into the medical record. For ascertaining the interval from the previous ectopic pregnancy until a subsequent conception, a calculation was performed using the date of the original surgery for ectopic pregnancy and a presumed conception based on a 40-week term gestation, a 12-week spontaneous or therapeutic abortion, and a 6-week repeat ectopic pregnancy.

Results

Two hundred and sixty-four patients had surgery for ectopic pregnancy during the study period July 1983 to March 1985. Seventy-six patients in the surgical groups evaluated had postoperative hysterosalpingograms. Fifty-two had salpingectomy (total and partial), 13 had salpingostomy, and 5 had mechanical tubal abortion. Six women had other procedures. Fifty-five (76.4%) of these patients had follow-up longer than 3 months. The follow-up time ranged from 3 to 41 months (mean, 23.8 months). Follow-up times for the three operative groups were not significantly different: 25.0, 21.3, and 19.3 months, respectively (Table I). The mean age of the patients was 23.4 years (25.2 years for women undergoing salpingectomy, 21.8 years for women undergoing salpingostomy, and 24.3 years for the tubal abortion group). The salpingostomy patients were significantly younger than the salpingectomy patients ($p = 0.027$).

The mean parity of the study patients was 1.09. At the time of their initial ectopic pregnancy, 60% of the patients were parous as follows: 25 (64.1%) of the salpingectomy group, 6 (50%) of the salpingostomy group, and 4 (100%) of the mechanical tubal abortion group.

A total of 209 women were lost to follow-up. To assess characteristics of these women in relation to our study population, we randomly sampled 80 of those who were lost to follow-up. The mean age of those women was 25.7 years, which is comparable with a mean age of 23.4 years for those women who have been followed up. The distribution of procedures for management of ectopic pregnancy was comparable between those women followed up and those lost to follow-up. Specifically, in the former group 31% underwent salpingostomy and 52% had salpingectomy. In the latter group, 35% had salpingostomy and 59% had salpingectomy.

During the follow-up period, 30 pregnancies occurred among the 55 patients. Twenty-four were intrauterine pregnancies and six were repeat ectopic gestations. Twenty-nine of the patients (52.7%) desired pregnancy. Of these, 20 patients (69%) achieved pregnancy (19 pregnancies were intrauterine and 18 were delivered at term). Nine of the 29 women desiring pregnancy (31.1%) have remained infertile. Ten patients who did not desire pregnancy became pregnant; five of the resultant ten pregnancies were intrauterine and five were ectopic (Table II).

Table II. Fertility status after previous ectopic pregnancy by desire for pregnancy

Desire for pregnancy	*Fertility status*	
	Pregnancy achieved	*No pregnancy achieved*
Pregnancy planned (29 patients)	20 (69%)	9 (31%)
Pregnancy unplanned (26 patients)	10 (39%) (5 IUP, 5 ectopic)	16 (62%)

IUP, Intrauterine pregnancy.

Table III. Subsequent fertility when pregnancy was desired after previous ectopic pregnancy by surgical management

Fertility status	*Surgical management*		
	Salpingectomy (n = 39)	*Salpingostomy (n = 12)*	*Tubal abortion (n = 4)*
Total pregnancies	15	3	2
Intrauterine pregnancies	14	3	2
Mean time to conception (mo)	12.2 ± 7.4	8.3 ± 3.0	10.7 ± 4.5

Table IV. Surgical findings among women with repeat ectopic pregnancy by previous surgical management and prior hysterosalpingographic findings

Previous surgical management	*Hysterosalpingographic findings*	*Findings at surgery for ectopic gestation*
Left salpingectomy	Contralateral patency	Right[2] tubal pregnancy
Left salpingostomy	Bilateral patency	Right tubal pregnancy
Left salpingostomy	Contralateral patency	Right tubal pregnancy
Right salpingostomy	Contralateral patency but located	Left tubal pregnancy
Left salpingostomy	Contralateral patency	Left tubal pregnancy
Left tubal abortion	Ipsilateral patency	Right tubal pregnancy

To evaluate pregnancy potential, we performed a subgroup analysis on that group of women desiring pregnancy (excluding those not desiring pregnancy, most of whom intermittently used barrier contraception). Among the 39 patients initially undergoing salpingectomy, 14 (60.8%) of the 23 women desiring pregnancy achieved an intrauterine pregnancy. Of the 12 patients who had salpingostomy, three desired and achieved pregnancy (100%). Hysterosalpingographic findings indicated at least one patent tube in 28 of 39 (71.8%) women in the salpingectomy group, 11 of 12 (91.7%) in the salpingostomy group, and of the women in the tubal abortion group, the 2 women desiring pregnancy conceived (100%) (Table III).

Six of the 55 women who were followed up experienced a repeat ectopic pregnancy. One such pregnancy occurred in a woman who had salpingectomy and who desired pregnancy. The other five ectopic gestations occurred among women not desiring pregnancy. It is noteworthy that five of the six ectopic pregnancies were found in the contralateral fallopian tube (Table IV).

Patients who had an intrauterine pregnancy without regard to desire for pregnancy (24) were compared with those unable to achieve a desired pregnancy (9), and those with repeat ectopic pregnancy (6) to determine whether any important differences could be discerned. The mean patient ages were not significantly different (24 ± 3.7, 23.6 ± 5.6, and 23 ± 2.1 years, respectively, for the three groups).

In each group similar numbers of women were parous: 16 (66%) of those with intrauterine pregnancies, 6 (66%) of those not achieving pregnancy, and 5 (83%) of those with repeat ectopic pregnancy. Follow-up times for the groups were 25.6 months for the intrauterine pregnancy group, 28.4 months for the infertility group, and 22.5 months in the repeat ectopic pregnancy group. The repeat ectopic pregnancy patients had significantly shorter follow-up time ($p = 0.31$).

Hysterosalpingographic patency was different for the pregnancy outcome groups. Patients with an intrauterine pregnancy had 83.4% patency. Those who did not become pregnant but desired pregnancy had 55% patency, and patients with repeat ectopic pregnancies had 100% patency. Intrauterine contraceptive device

Table V. Fertility status of women with prior ectopic pregnancies of history of intrauterine contraceptive device use and history of pelvic inflammatory disease

History	*Fertility status*		
	Intrauterine pregnancy ((n = 24)	*Not pregnant but desiring pregnancy (n = 9)*	*Repeat ectopic pregnancy (n = 6)*
IUD use	3 (13%)	1 (11%)	—
PID	8 (33%)	2 (22%)	2 (33%)
Both	5 (21%)	2 (22%)	—
Neither	8 (33%)	3 (33%)	4 (67%)
Unknown	1 (.5%)	1 (11%)	—

IUD, Intrauterine contraceptive device; *PID*, pelvic inflammatory disease.

Table VI. Fertility status of women with prior ectopic pregnancies by previous surgical management

Previous surgical management	*Fertility status*		
	Intrauterine pregnancy (n = 32)	*Not pregnant but desiring pregnancy (n = 9)*	*Repeat ectopic pregnancy (n = 6)*
Salpingectomy	18 (75%)	9 (100%)	1 (17%)
Salpingostomy	4 (17%)	0	4 (66%)
Tubal abortion	2 (8%)	0	1 (17%)

Table VII. Fertility status after prior ectopic pregnancy by hysterosalpingographic findings

	Intrauterine pregnancy achieved whether or not planned	*No pregnancy achieved when pregnancy desired*
Hysterosalpingogram patent	20 (83%)	5 (55%)
Hysterosalpingogram nonpatent	4 (17%)	4 (45%)
Total	24 (100%)	9 (100%)

use and pelvic inflammatory disease history was not significantly different for the three groups (Table V). However, there was a difference noted by type of surgical procedure performed (Table VI). All of the women not pregnant but desiring pregnancy during the follow-up period had salpingectomy. Those women experiencing ectopic pregnancy were most likely to have had salpingostomies.

We evaluated the usefulness of hysterosalpingography in predicting fertility status in the 33 patients who achieved an intrauterine pregnancy or were desirous of a pregnancy (Table VII). Of the 25 women with a patent hysterosalpingogram, 20 (80%) achieved an intrauterine pregnancy. Of the eight patients with nonpatent hysterosalpingographies, four (50%) become pregnant. Although patency is a good prognostic indicator of ability to conceive, nonpatency is not necessarily a predictor of poor outcome. Of the women not pregnant but desiring pregnancy in the following period, five (55.5%) had patency.

Comment

Our findings suggest that most women desiring pregnancy after previous ectopic gestations can achieve an intrauterine pregnancy within a short time interval regardless of initial surgical management.

A substantial percentage (38.6%) of women who did not plan pregnancy nevertheless became pregnant. Of those women, a relatively higher percentage (50%) had ectopic gestations. A total of six (10.9%) repeat ectopic pregnancies were experienced by our 55 study patients. Other reports have identified comparable rates of 6% to 27%.[2-7]

Women desiring but unable to achieve pregnancy were more likely to have undergone salpingectomy, but those who were experiencing repeat ectopic pregnancy were more likely to have undergone salpingostomy. These findings suggest that salpingostomy is associated with an increased risk of subsequent ectopic pregnancy. Three of 12 women in our series who had salpingostomy desired and achieved an intrauterine pregnancy.

However, four of the nine women not desiring pregnancy experineced ectopic gestations. Only one of these had bilateral patency on postoperative hysterosalpingography. Three had contralateral patency; two of these patients and one with bilateral patency had their ectopic gestations in the contralateral tube. Whether linear salpingostomy on one tube might increase the risk of ectopic pregnancy in the contralateral tube must therefore be questioned. All in our series who underwent salpingostomy had unruptured ampullary pregnancy. By contrast, women with salpingectomy had isthmic or ruptured ampullary pregnancies. Although we are not aware of any plausible mechanism to provide a unifying hypothesis, it is possible that some determinant of the indications for salpingostomy is associated with an increased risk of ectopic pregnancy in the contralateral tube. Alternatively, salpingostomy itself might somehow result in increased risk in the contralateral tube. Possible mechanisms include operative site hemorrhage or postoperative adhesions.

One of the objectives of our study was to determine the usefulness of postoperative hysterosalpingography in predicting subsequent fertility potential. Contralateral tubal patency demonstrated by hysterosalpingography appears to be a good prognostic indicator for achieving intrauterine pregnancy. Approximately 80% of women with tubal patency on hysterosalpingography achieved an intrauterine pregnancy; in a report by DeCherney et al.,[2] 50% of patients did achieve intrauterine pregnancy. By contrast, in our study one half of those with findings of nonpatency still achieved an intrauterine pregnancy. Whether this difference is a result of tubal spasm, technique, or other factors requires additional investigation.

Our findings may not be generalizable to all women experiencing ectopic gestations. The 264 women initially enrolled in our follow-up investigation were primarily indigent, urban residents, many of whom were transient residents and most of whom were black. However, we do have some confidence that our findings are generalizable to the Grady Hospital population. Although only 76 women returned for postoperative hysterosalpingographies as advised, motivation, (as opposed to other selection factors), appears to be reasonable. We have no indication of important selection biases. Furthermore, we were able to follow up 75% of these women by telephone. Those we did not interview could not be located; no woman refused the interview. The lack of apparent bias in selection of those followed up gives us further confidence in generalizing our findings to the Grady Hospital population. Further studies elsewhere should determine whether findings in our population are generalizable to other racial and socioeconomic groups.

Editors' note: This manuscript was revised after these discussions were presented.

Discussion

Dr. Wallace Nunley, Charlottesville, Virginia. Your findings were similar to those that we reported last year regarding the higher repeat ectopic rate in the salpingotomy patients versus those with salpingectomy. Although the numbers were small, do you have additional information about the repeat ectopic pregnancy rate in those patients who had conservative tubal surgery on the sole remaining tube? When you said that the hysterosalpingography revealed nonpatent tubes and that there was a 16% intrauterine pregnancy rate, I assume that we are discussing complete nonfilling of the tube as opposed to a distal obstruction.

Dr. H. Oliver Williamson, Charleston, South Carolina. Did you reexamine the hysterosalpingograms for salpingitis isthmica nodosa on those patients who had ectopic pregnancies?

Dr. Mitchell (Closing). Dr. Nunley, most of the obstructions were distal occlusions. In reviewing the hysterosalpingograms, if we did find a cornual occlusion, it might have been caused by spasm or technique, and we could not really ascertain this since we had different individuals performing the hysterosalpingography. We could not verify one specific reason for our good pregnancy rate. We cannot tell the patient that sheis not going to achieve a pregnancy, and we have been advising patients of that information. I really do not have an answer for your other question.

Dr. Williamson, we did attempt to restudy the hysterosalpingograms. We found that the patients who had salpingectomies and then had a repeat ectopic pregnancy primarily cornual ectopic pregnancies correlating with the diagnosis of salpingitis isthmica nodosa. Essentially, the majority of those who had salpingectomies had cornual occlusion, and the repeat ectopic pregnancies in that particular group were interstitial ectopic pregnancies.

Effects of clomiphene citrate on episodic luteinizing hormone secretion throughout the menstrual cycle

David F. Archer, MD, Glen Hofmann, MD, PhD, Robert Brzyski, MD, PhD, Barbara Ross, RN, BSN, Richard T. Scott, Jr., MD, Christine B. Philput, PhD, Sergio Oehninger, MD, and J. Catesby Ware, PhD

Norfolk, Virginia

Pituitary luteinizing hormone secretory dynamics (pulse frequency and amplitude) were evaluated in eight normal women administered clomiphene citrate or placebo. After 5 days of treatment clomiphene citrate was found to increase mean luteinizing hormone secretion by increasing the amount of pituitary luteinizing hormone released per pulse. No change in pituitary luteinizing hormone interpulse interval was found in the follicular phase of the cycle, although a faster pulse frequency in the luteal phase was found after clomiphene citrate when compared with placebo. No differences were found in the luteal phase (pulse frequency, amplitude, and mean luteinizing hormone level) after clomiphene citrate versus placebo in the volunteers. These data suggest that the principal mechanism of action of clomiphene citrate is an increase in the concentration of hypothalamic gonadotropin releasing hormone into the hypothalamic-pituitary portal circulation, with a resultant increase in pituitary luteinizing hormone secretion. (Am J Obstet Gynecol 1989;161:581-92.)

Key words: Clomiphene citrate, pituitary luteinizing hormone secretion, normal women

Clomiphene citrate, an antiestrogen, has been used extensively to initiate follicular development in anovulatory women. The principal mechanism of action appears to be via the hypothalamic-pituitary axis resulting in an increase in serum follicle-stimulating hormone (FSH) and luteinizing hormone (LH) levels.[1] Recent evidence suggests that clomiphene citrate increases the frequency of episodic pituitary LH secretion in normal women.[2] An alteration in pituitary LH pulse frequency implies a hypothalamic site of action of clomiphene citrate.

The use of clomiphene citrate in the treatment of anovulatory infertility and/or luteal phase deficiency has been shown to result in the persistence or occurrence of luteal phase deficiency.[3] The administration of clomiphene citrate in large doses (200 mg/day for 5 days) also has been associated with a short luteal phase in normal women.[4] An increase in the follicular phase pituitary LH pulse frequency has been described in women with histologic evidence of luteal phase deficiency.[5]

The current study was undertaken because of the potential relationship between clomiphene citrate administration, an increase in pituitary LH pulse frequency, and the occurrence of luteal phase deficiency. The study design was to determine pituitary LH episodic release in the follicular and luteal phases of normal women who were administered clomiphene citrate. Any alterations in the parameters of pituitary LH episodic release would then be correlated with histologic and hormonal evidence of luteal phase deficiency.

Material and methods

Volunteers. Eight female volunteers who were between the ages of 18 and 35 and had regular cyclic menstrual bleeding episodes were asked to volunteer for this study. The protocol and informed consent had been approved by the Institutional Review Board of Eastern Virginia Medical School. A written informed consent was obtained from each volunteer before enrollment in the study. None of the women had used any exogenous steroid in the preceding 3 months. None of the volunteers had any evidence of gynecologic problems by history or physical examination, and they were

*Follicular interval is the number of days from onset on menstruation to the urinary LH surge.
†Luteal interval is the number of days from a urinary LH surge until the onset of the next bleeding episode.
‡Total is the number of days from onset of menstruation to onset of next menses.

all in good health. Their demographic backgrounds and menstrual cycle data are given in Table I.

Study design and medication schedule. The study design was a double-blind randomized administration of clomiphene citrate (50 mg twice a day) versus placebo (one tablet twice a day) taken orally for 5 days beginning on day 5 after the onset of menstruation. The oral medication, both clomiphene citrate and placebo, was supplied by a registered pharmacist from a local pharmacy to the Clinical Research Coordinator in similar packages in a random order. The composition of each package was blinded to the study coordinator and the other investigators. Each volunteer, on entering the study, was assigned a sequential number that was related to the medication dispensed. Each volunteer was administered a course of medication in one menstrual cycle, then was not treated in the next menstrual cycle. In the third cycle the alternate medication was used.

Throughout each investigative cycle, a basal body temperature recording was performed. The midcycle urinary LH surge was determined by assessing morning urine specimens from menstrual days 12 to 18 with a commercial kit (Ovustik, Monoclonal Antibodies, Inc., Mountain View, Calif.). Daily blood samples were obtained from menstrual day 5 to the onset of the next menstrual bleeding episode in all volunteers.

The volunteers were randomized into either the follicular or the luteal phase investigation of episodic LH secretion at the time of their entry into the study. Four of the volunteers were evaluated on the last day of medication administration (day 9 of the cycle) in each treatment cycle. The other four volunteers were evaluated on day 10 after a urinary LH surge in the luteal phase of the two treatment cycles.

All volunteers underwent an endometrial biopsy on day +11 after the urinary LH surge in both treatment cycles.

Sampling schedule for the assessment of episodic LH secretion. Each volunteer was admitted to the Sleep Disorders Center of Sentara Norfolk General Hospital at 6 PM on the selected menstrual cycle day on the basis of her group assignment. An indwelling intravenous catheter was inserted into an arm vein and the patency was maintained with a slow infusion of normal saline solution containing 10,000 IU of heparin per 1000 ml of fluid. An extension catheter that was led through a wall porthole allowed sampling to take place from an adjacent room without disturbing the volunteers' sleep. Peripheral venous samples were obtained every 10 minutes for 12 hours from each volunteer. Each blood sample was allowed to clot at room temperature; then serum was collected by centrifugation and stored at −20° C until analyzed.

Evaluation of the menstrual cycle. Daily peripheral venous blood samples were obtained from each volunteer from day 5 of menstruation until the onset of the next menstrual period in each treatment cycle for analysis of 17β-estradiol, progesterone, and LH. Each blood sample was handled as described above.

During the treatment cycles each volunteer collected a morning urine specimen beginning on day 12 of the menstrual cycle; this specimen was tested at home for LH with the Ovustik LH test kit. This procedure was performed until the LH surge was demonstrated or day 20 was reached.

Each volunteer also underwent an endometrial biopsy on day 11 after the identified urinary LH surge. The endometrial tissue obtained was examined histologically and a date assigned according to published criteria.[6]

Multiple venous sampling was performed on day 9 to day 10 of the cycle and day +10 to +11 after a urinary LH rise between 6 PM and 7 AM.

Superscripts represent differences between means (*a, b, c, d, e*, $p = 0.0001$; *f*, $p = 0.02$).

Estimation of 17β-estradiol, progesterone, and LH. Peripheral levels of 17β-estradiol, progesterone, and LH were assessed with commercially available radioimmunoassay kits. Serum 17β-estradiol levels were determined with a kit obtained from Radioassay Systems Laboratory (Carson, Calif.); the within-assay coefficient of variation was 11% and the between-assay variation was 7%. Progesterone was estimated with a radioimmunoassay kit from Diagnostic Products, Inc. (Los Angeles). The within-assay coefficient of variation was 12.5%, 10.0%, and 6.7%, respectively, for low, mid, and high controls, while the between-assay coefficient of variation was 17%, 13.5%, and 7.0% for low, mid, and high controls. Serum LH was determined with a kit from Leeco Co. (Southfield, Mich.); the within-assay coefficient of variation was 17.7% and 9.8% for the low and high controls, and the between-assay coefficient of variation was 29.4% and 17.7%, respectively, for low and high controls.

Evaluation of episodic LH secretion. Episodic release of LH was evaluated with the program PULSAR, edition 1983.1 of Merriam and Wachter,[7] as modified for the IBM-PC by Gitzen and Ramirez.[8] We modified the program as described by Mais et al.[9] by determining the coefficient of variation at different dose levels of LH and defined an LH pulse as an increment in LH concentration exceeding the preceding nadir value by 3.8 times the coefficient of variation.

Statistical analysis. The parameters of the episodic pituitary LH secretion were compared between placebo and clomiphene citrate–treated cycles in both the follicular and the luteal phases. An analysis of variance was used to determine if there were any significant interactions. When significant interactions were found with the analysis of variance, this was followed with Student's *t* test for significant differences. These computations were performed with the SAS program under the general linear model on a VAX/VMS computer. A paired analysis was performed on the daily serum 17β-estradiol, progesterone, and LH levels with STAT Graphics statistical software (Statistical Graphics Corporation, Rockville, Md.) on an IBM-PC.

Results

Episodic pituitary LH release

Effects of clomiphene citrate

FOLLICULAR PHASE. Mean peripheral LH levels on the fifth day of active therapy (day 9 to 10 of the cycle) during the 12-hour sampling interval were significantly increased during the administration of clomiphene citrate compared with placebo ($p = 0.0001$) (see Table II, Fig. 1, *A*). The mean amplitude of each identified LH pulse was statistically increased during clomiphene citrate administration compared with placebo ($p = 0.0001$, Table II, Fig. 1, *A*). The frequency of the pituitary LH pulse(s) was expressed as the interpeak interval and was not significantly different between placebo and clomiphene citrate (36 vs. 40 minutes, respectively, Table II). There was no significant difference in the duration of the identified LH peaks with either treatment (data not shown).

LUTEAL PHASE. Mean LH levels on luteal days +10 to +11 after the identified urinary LH rise during the 12-hour sampling interval were not significantly different between the placebo and clomiphene citrate–treated cycles (see Table II, Fig. 1, *B*). There was no difference in the amplitude of the identified LH peaks in the luteal investigation with either treatment (see

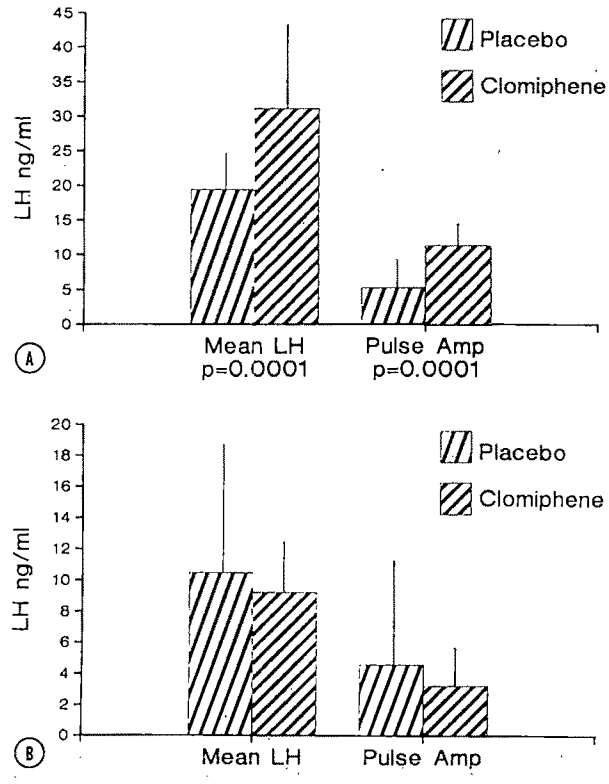

Fig. 1. A, Mean LH levels and mean pulse amplitude of identified peaks in normal women receiving placebo or clomiphene citrate 100 mg/day from day 5 to day 9 of menstrual cycle. See text for details of sampling, which was performed in the follicular phase (day 9) of the cycle. **B,** Mean serum LH levels and mean pulse amplitude of identified LH peak in normal women while receiving either a placebo or clomiphene citrate 100 mg/day from day 5 to day 9 of cycle. These values were obtained on luteal day +10 after urinary LH rise. See text for details of sampling.

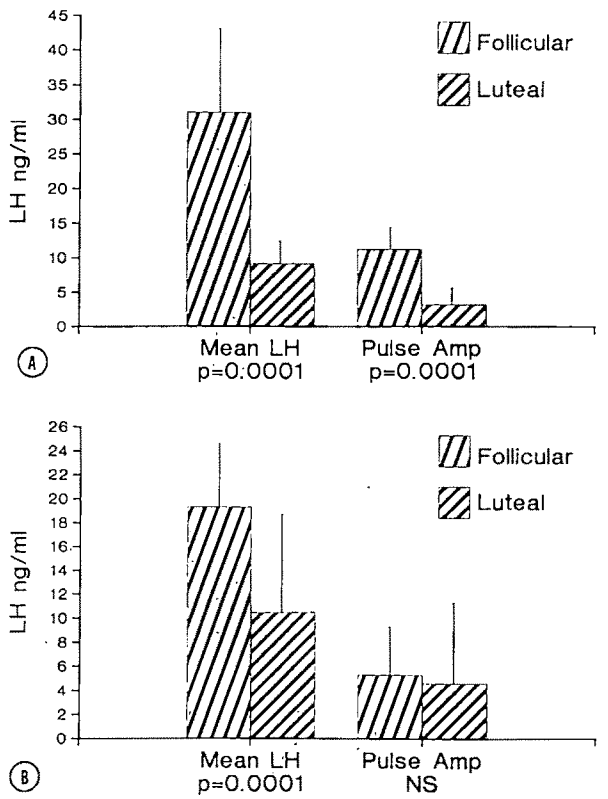

Fig. 2. A, Comparison of mean LH levels and pulse amplitude between follicular day 9 and luteal day +10 after the LH rise in normal women while receiving placebo from days 5 to 9 of menstrual cycle. **B,** Comparison of mean LH amplitude of identified LH pulses between follicular and luteal phases of women who were administered clomiphene citrate 100 mg/day between days 5 and 9 of menstrual cycle.

Table II, Fig. 1, *B*). The interpeak interval was shorter in the volunteers who had received clomiphene citrate (37 minutes) compared with placebo (50 minutes) during the luteal phase sampling (Table II, $p = 0.03$).

A comparison of the mean LH levels between the follicular and luteal phases was performed for both placebo and clomiphene citrate. The mean LH levels were significantly higher in the follicular phase than in the luteal phase for both placebo (19.37 vs. 10.50 ng/ml; $p = 0.0001$) and clomiphene citrate (31.11 vs. 9.23 ng/ml; $p = 0.0001$) (see Table II, Fig. 2). This finding was associated with a decreased LH peak amplitude only in the clomiphene citrate volunteers in the luteal phase ($p = 0.0001$) compared with the follicular phase (Table II, Fig. 2, *B*), whereas there was no difference in pulse amplitude between follicular and luteal phases of the placebo cycle (Table II, Fig. 2, *A*). The interpeak intervals were significantly different between follicular and luteal phases in the placebo treatment groups. There was no difference in the interpeak interval in the clomiphene citrate volunteers between the follicular and luteal phases. There was a significant difference in the interpeak interval in the clomiphene citrate group (37 minutes) compared with the placebo group (50 minutes) during the luteal phase ($p = 0.02$, Table II).

Menstrual cycle hormonal changes. Each volunteer had daily blood samples drawn beginning on day 5 of the cycle and proceeding until the onset of the next menstrual bleeding episode. These serum samples were analyzed for 17β-estradiol, progesterone, and LH. The identified midcycle serum LH peak was used as the reference point for comparison of the steroid hormone levels in both follicular and luteal phases in all volunteers. The daily serum LH levels were significantly increased during clomiphene citrate administration compared with placebo in all of the volunteers ($p = 1 \times 10^{-6}$, Fig. 3). The height of the LH midcycle peak between placebo and clomiphene citrate cycles was not statistically different (see Fig. 4, *A*). Clomiphene

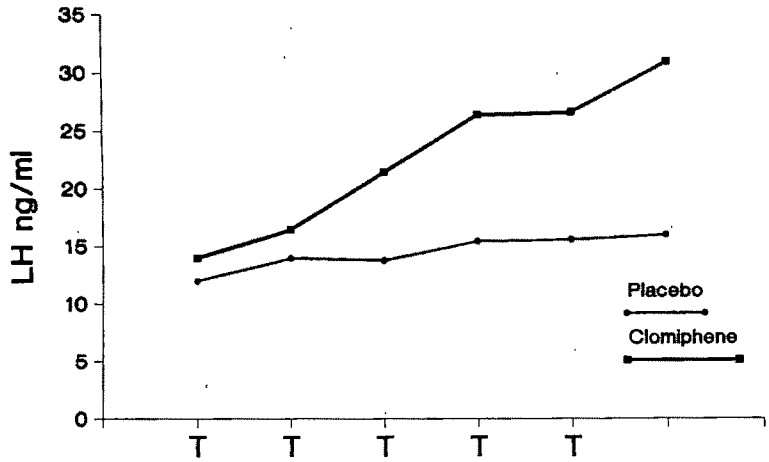

Fig. 3. Serum LH (nanograms per milliliter) levels during 5 days of treatment, placebo or clomiphene citrate 100 ml/day, and the day after medication was stopped.

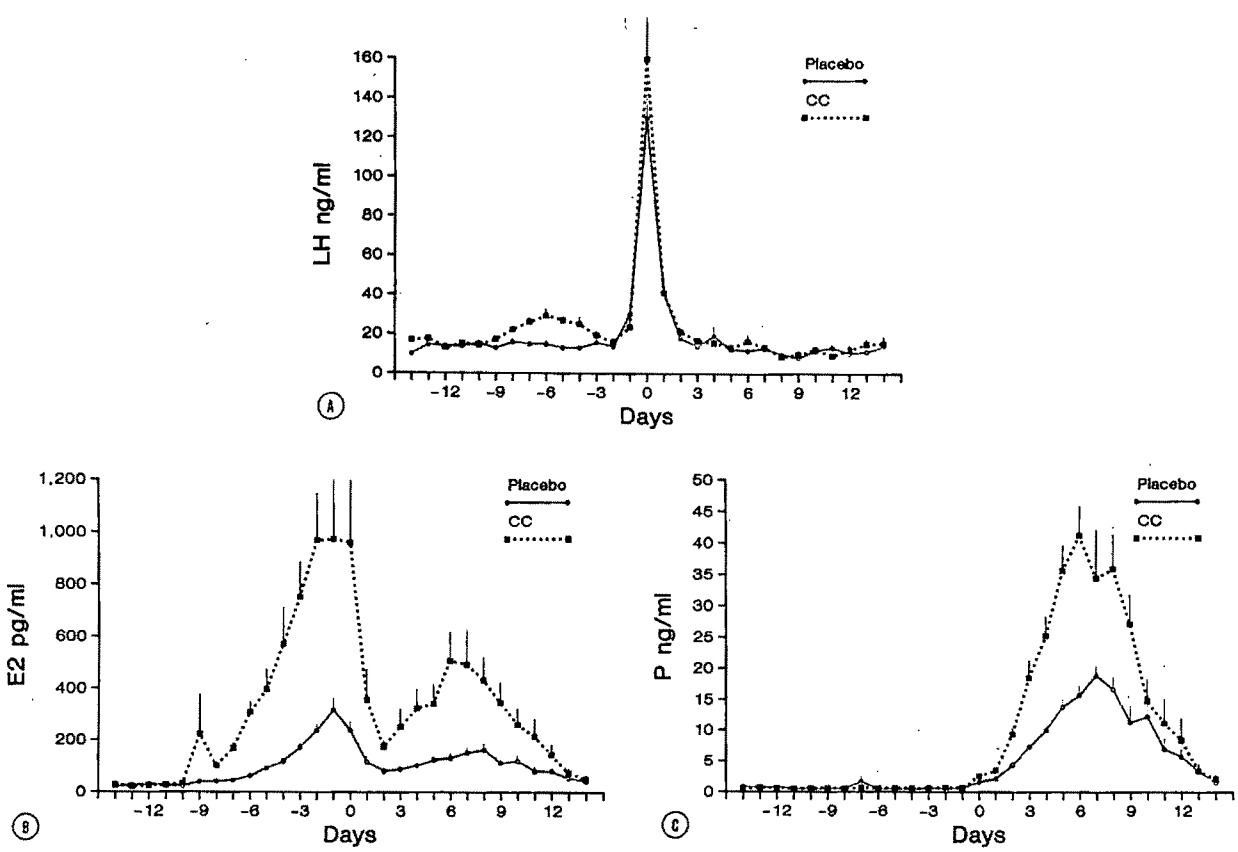

Fig. 4. A, Daily serum LH (nanograms per milliliter) levels from day 2 of cycle in women who received either placebo or clomiphene citrate 100 mg/day from days 5 to 9 of menstrual cycle. Data have been normalized to LH peak. **B,** Daily serum 17β-estradiol (picograms per milliliter) levels in normal volunteers, who took either placebo or clomiphene citrate 100 mg/day from days 5 to 9 of cycle. All values have been normalized to day of serum LH surge (day 0). **C,** Daily serum progesterone *(P)* (ng/ml) levels in normal volunteers who took either placebo or clomiphene citrate 100 mg/day from day 5 to 9 of cycle. All values have been normalized to day of serum LH surge (day 0).

citrate administration also significantly increased the mean 17β-estradiol levels from day −8 until the LH peak, when compared with the placebo treatment (see Fig. 4, *B*). A paired analysis of these data demonstrated a statistically significant difference in the follicular phase ($p < 1 \times 10^{-7}$) and luteal phase ($p < 2 \times 10^{-12}$, Fig. 4, *B*). Because there were occasional missing data points in one cycle of a volunteer, on comparison with her second cycle, the area under the curve for 17β-estradiol was then estimated by the trapezoidal method. When this estimate was performed, the area under the 17β-estradiol curve for clomiphene citrate was still significantly greater than placebo ($p = 0.02$). Serum progesterone levels were also markedly elevated during the luteal phase in the clomiphene citrate volunteers compared with placebo ($p < 1 \times 10^{-7}$) (see Fig. 4, *C*).

Menstrual cycle length and luteal phase adequacy. There were no significant changes in the menstrual cycle interval in the volunteers during the placebo or clomiphene citrate administration (Table I). All volunteers had cycle intervals of 27 to 31 days before treatment. During treatment, one volunteer had a menstrual interval of 36 days while receiving clomiphene citrate; this was secondary to a prolonged follicular phase (Table I). None of the other volunteers had any evidence of follicular phase dysfunction. There was no discernible difference in the length of the luteal phase (LH urinary rise to menses) in any of the volunteers with either treatment (Table I). The cycle day of the serum and urinary LH rise was not different between the two treatments although the standard deviation of the mean interval from onset of menses to peak LH levels was three times larger in the placebo group than in the clomiphene citrate group (data not shown).

Histologic examination of endometrial biopsy specimens obtained in both the placebo and clomiphene citrate treatment cycles on the morning of day +11 after the urinary LH rise were assigned dates according to previously reported criteria.[6] All biopsy specimens were read as day 22 to 25 of the cycle. There was no histologic evidence of luteal phase deficiency in any of these biopsy specimens.

Comment

This study has found that there is a significant increase in pituitary LH secretion in women who are taking clomiphene citrate between days 5 and 9 of the follicular phase of the menstrual cycle. These data are in agreement with other reports that the mode of action of clomiphene citrate in stimulating the initiation of folliculogenesis is via a hypothalamic-pituitary mechanism, which results in an increased gonadotropin secretion.[1, 10, 11] The increase in serum LH levels could be brought about through at least three different mechanisms. These are: (1) an increase in the total amount of LH released per pulse, (2) an increase in the frequency of pulses per unit time, and (3) a change in the pituitary sensitivity to the endogenous gonadotropin releasing hormone. These parameters should be considered assuming that there are no significant changes in peripheral metabolism or excretion of the hormone under investigation.

It appears that the total amount of LH released per pulse is the explanation for the increased serum LH level found during clomiphene citrate administration. The amplitude of the identified LH pulses was higher in the follicular phase of the cycle with clomiphene citrate treatment (Fig. 1, *A*). Increased pituitary hormonal secretion has been found to be related to an increase in the quantitative amount of hormone released per episode on the basis of deconvolutional analysis.[12] Our data support this concept that the increase in serum hormone concentration is due to an increased release of hormone with each secretory episode.

We were unable to discern a significant difference in pituitary interpeak interval between the women receiving placebo and those given clomiphene citrate. This is in contradistinction to a previous report that demonstrated an increase in pulse frequency in the follicular phase of the cycle in women.[2] In this study pulse frequencies were compared before and after ingestion of clomiphene citrate and placebo in the volunteers. These authors did not find a significant difference in the pulse frequency on the same cycle day between women receiving placebo and those given clomiphene citrate. Other investigators have described a small but significant increase in pulse frequency in women who were administered clomiphene citrate.[13]

In the current study we were not able to show any difference in pulse frequency on the basis of interpeak interval between clomiphene citrate and placebo on cycle days 9 to 10. These data suggest that clomiphene citrate does not have an effect on the hypothalamic pulse generator. The reason for the differences between our study and the other may be explained by the fact that we were sampling overnight. A slowing of LH pulse frequency has been described to occur in the follicular phase of the cycle with sleep. We have not specifically addressed the issue of pituitary LH pulse frequency in the awake state versus the asleep state in this study, although the data are under analysis. Alternatively, the longer duration of sampling (12 hours) in our study compared with 4 and 9 hours, respectively, and the more frequent venous sampling interval (10 minutes) could contribute to a more accurate assessment of pulse frequency.[13, 14, 21]

We found a high frequency of pituitary LH pulses on days 9 to 10 of the menstrual cycle. The mean interpeak interval in the follicular phase of the cycle was 40 minutes in the clomiphene citrate–treated volunteers; this is not different from that with placebo (Table II). We believe that the high frequency of identified

LH pulses was due to the sensitivity of the PULSAR program. Because of the large coefficient of variation in the radioimmunoassay associated with the low levels of LH, we determined the within-assay coefficient of variation with low, medium, and high LH control and constructed a binomial equation from these data points.[9] Using these coefficients of variation we reran the data and used the criterion that an increase of LH over the preceding nadir value of >3.8 times the coefficient of variation was needed to identify a LH peak. When this modification was performed, the increased number of peaks presented in the current study were identified. We believe that the increased pulse identification is related both to the sensitivity of the PULSAR program and to the duration and frequency of the sampling. These data are in accordance with the reported paradigm indicating that glandular hormonal secretion is characterized by a short-lived rapid burst of secretory activity.[12]

The increased pituitary LH secretion per pulse may be secondary to an increase in the amount of endogenous hypothalamic gonadotropin releasing hormone released. Clomiphene citrate has been shown to increase the in vitro release of gonadotropin releasing hormone from isolated perfused rat hypothalami.[15] Increased quantities of circulating immunologic gonadotropin releasing hormone have been detected in peripheral sera of women who were administered clomiphene citrate.[16] The quantity of pituitary LH released was found to be directly correlated with the amount of exogenous gonadotropin releasing hormone administered in men with hypogonadotropic hypogonadism associated with a gonadotropin releasing hormone deficiency.[17] Other investigators have found that exogenous gonadotropin releasing hormone administration (10 μg) does not result in a significant difference in the quantity of pituitary LH release in normal women studied at the same time in the menstrual cycle, either not receiving treatment or receiving clomiphene citrate.[13] We believe that these data and our own from the current study are compatible with the hypothesis that there is an increased quantity of hypothalamic gonadotropin releasing hormone being released during clomiphene citrate administration in normal women.

Another possibility is that clomiphene citrate could alter the pituitary sensitivity to endogenous gonadotropin releasing hormone. Clomiphene citrate was found to increase the pituitary secretion of LH only minimally with an in vitro superfusion technique.[15] However, pituitary cells exposed to clomiphene citrate in vitro were shown to have an increased sensitivity to gonadotropin releasing hormone.[1] Further, clomiphene citrate, an antiestrogen, could result in endocrine changes similar to those present in a postmenopausal woman. Increased pituitary LH secretion with large-amplitude LH pulses is known to occur in women with ovarian failure.[18] Further, studies in castrated rats have found that there is a decrease in the hypothalamic-pituitary portal concentration of gonadotropin releasing hormone, with an increase in both the number and the sensitivity of pituitary gonadotropic cell gonadotropin releasing hormone receptors.[19] Although these reports do indicate a direct effect of clomiphene citrate on the pituitary gonadotropic cell, they imply that the effect, if present, is minimal.

We did not find any significant differences in luteal phase mean serum LH levels and LH amplitude between the placebo and clomiphene citrate cycles with sampling performed on LH surge day +10 during the luteal phase. The effect of progesterone on hypothalamic-pituitary function is believed to be a slowing in the hypothalamic pulse generator with a concomitant increase in pulse amplitude.[21] Our data, however, are at variance with other reports of investigations in both subhuman primates and humans relative to the increased pulse amplitude in the luteal phase of the cycle.[22, 23] There does appear to be a reduction in both mean LH levels and peak amplitude in the late luteal phase of the cycle in these studies.[22, 23] Our luteal sampling was performed on the tenth day after the urinary LH surge and should be considered late luteal phase. There also appears to be a decrease in the LH pulse amplitude at night in women during the late luteal phase, although the published data are too sparse to make any meaningful conclusions.[23] We believe that the timing of our investigation of pituitary secretory dynamics i.e., at night and in the late luteal phase, explains our current findings.

The pituitary LH interpeak interval was less in the clomiphene citrate volunteers than in those receiving placebo in the luteal phase (Table II). The cause of this latter finding is not known but could be related to an increased retention of clomiphene citrate in the body.[1] Studies have indicated that clomiphene citrate can be present for up to 6 weeks after administration.[1] The administration of clomiphene citrate in the luteal phase also has been found to result in an increased LH pulse frequency.[20] These data suggest that the decreased luteal phase interpeak interval in the volunteers may be secondary to the presence of clomiphene citrate.

The clinical parameters used to determine menstrual cycle interval did not demonstrate any significant differences between placebo and clomiphene citrate. Specifically we did not find any alteration in the interval in days of the follicular or luteal phases (see Table I). Other investigators who have used clomiphene citrate for initiation of follicular maturation in anovulatory or normal women report a delay in the LH surge related to the use of clomiphene citrate.[1, 10, 11] In a study of normal women undergoing clomiphene citrate therapy for in vitro fertilization the follicular phase was increased by 1 day in comparison with the untreated cy-

cle.[24] Although we looked for this, no significant difference was found in the interval from onset of menses to serum LH surge or from onset of treatment to serum LH surge. We were impressed with the finding that there was a smaller standard deviation in the interval from menses to LH surge in the clomiphene citrate–treated women compared with those given placebo. We feel that this indicates that clomiphene citrate results in a more concordant midcycle LH release, possibly related to the follicular development.

High doses of clomiphene citrate administered to subhuman primates have been found to inhibit follicular response and retard the occurrence of the midcycle LH surge. Only one of the women in this study had evidence of a prolonged follicular phase and this occurred during the use of clomiphene citrate (volunteer 9, Table I).[25]

There was a highly significant increase in the serum 17β-estradiol levels in the women while they were receiving clomiphene citrate (Fig. 4, *B*). The serum 17β-estradiol levels in anovulatory women during and after administration of clomiphene citrate have been reported to be on the order of 300 to 400 pg/ml.[1, 10] An evaluation of the serum 17β-estradiol levels in normal women who were undergoing controlled ovarian hyperstimulation for in vitro fertilization indicate a large increase in their serum 17β-estradiol levels.[17, 24] These data would imply a potential follicular resistance to or dysfunction with endogenous gonadotropins in anovulatory women. The large amount of clomiphene citrate used for initiation of follicular development in some women could inhibit ovarian folliculogenesis as described above, but there may be an ovarian dysfunction to explain the lower levels of 17β-estradiol found during clomiphene citrate administration in anovulatory women.[25] Alternatively, follicular development could be retarded in the anovulatory women as an explanation for the lower 17β-estradiol levels found during clomiphene citrate treatment.

Despite the increased serum concentrations of 17β-estradiol the LH surge was not advanced in the women as determined by both the serum LH levels and the urinary LH surge. In fact, in all but two women the serum LH peak coincided with the urinary LH surge (data not shown), and there was no difference in the height of the LH midcycle peak between the two treatments.

There were no discernible differences in the luteal phase lengths between the two treatments. The use of clomiphene citrate in high doses in normal women along with exogenous 17β-estradiol has been reported to cause a shortened luteal interval. The luteal interval on the basis of the day of the urinary LH surge to the onset of the next bleeding episode ranged from 10 to 15 days. Two of the women had luteal lengths of 10 and 11 days, respectively (volunteers 3 and 5), during a placebo and a clomiphene citrate–treated cycle.

The serum progesterone levels during the luteal phases were significantly higher in the women who had received clomiphene citrate. On the basis of the serum progesterone levels there was no evidence for either a luteal phase inadequacy or a shortened luteal interval. The endometrial biopsies that were performed on day +11 after the urinary LH surge were compatible with day 23 to day 25 of the cycle, and there was no histologic evidence of luteal deficiency. The exact incidence of luteal phase deficiency is difficult to assess but appears to be on the order of 2% to 3% in infertile women.[3] Clomiphene citrate has been thought to induce a luteal phase deficiency in both normal and infertile women. However, we were unable to find any evidence of luteal phase deficiency in the normal volunteers in this small series.

In summary, we have shown that clomiphene citrate results in an increased serum LH level in the follicular phase of the cycle in normal women. The increase appears to be related to an increased quantitative release of pituitary LH per pulse, since we found an increased amplitude of the identified peaks but no discernible change in pulse frequency.

Our data also indicate that luteal phase pituitary LH episodic secretion is not independent of the follicular phase administration of clomiphene citrate. We found a statistically different interpeak interval in the luteal phase of the women who received clomiphene citrate when compared with those given placebo, implying a long duration of effect of clomiphene citrate.

We acknowledge the assistance of Cindy Anderson, RN, MSN, FNC, Janice Hammond, J-G Hsui, MD, and Ms. Pauline Clynes.

Discussion

Dr. Mary G. Hammond, Chapel Hill, North Carolina. Although clomiphene citrate has been in use for the induction of ovulation for almost 30 years, the mechanism of action of this very useful drug continues to be debated. This antiestrogen, which was initially studied as a contraceptive and then introduced for the induction of ovulation in anovulatory women, has found increasing utility in treatment of women with evidence of ovulation. It is being used in the treatment of luteal phase dysfunction, and it is finding increasing usefulness in induction of multiple follicular development, in in vitro fertilization, and at present in some centers for multiple follicle development and washed intrauterine insemination in the treatment of male factor and unexplained infertility.

Essentially three mechanisms have been suggested as possible mode of action for clomiphene.[1] The first is by an interaction with hypothalamic estrogen receptors, leading to an increase in gonadotropin releasing hormone stimulation of the pituitary, resulting in a rise in circulating levels of FSH and LH, and stimulating follicle recruitment. The second is by increasing sensitivity of the pituitary gland to gonadotropin releasing hormone secretion, also leading to an increase in FSH and LH concentrations. The third proposed that clomiphene interferes with steroidogenesis in the ovary, reducing concentrations of circulating estrogens and again, through the hypothalamic mechanism, leading to an increase in gonadotropin releasing hormone production and a subsequent rise in gonadotropins. Two out of three of these mechanisms postulate a change in gonadotropin releasing hormone secretion at the hypothalamic level.

It would theoretically be possible to increase gonadotropin releasing hormone secretion by two methods. One would be by increasing the amplitude of the gonadotropin releasing hormone release. The second would be by increasing the frequency of gonadotropin releasing hormone pulses. An increase in pulsatility of gonadotropin releasing hormone would lead to an increased frequency of LH peaks in the circulation. An increase in the amplitude of the gonadotropin releasing hormone stimulation would lead to an increased amplitude of LH peaks in the serum.

The second mechanism, an effect on the pituitary gland, would lead to an increased sensitivity to the gonadotropin releasing hormone pulses and therefore to an increase in amplitude, but not frequency, of LH pulses.

The intent of this article was to evaluate further the effect of clomiphene citrate on LH pulse characteristics in normal women. These characteristics have been previously evaluated in the follicular phase. However, there are no reports of an evaluation in the luteal phase. In addition, the authors looked at the period of sleep as opposed to the daylight hours that had been previously studied. They concluded that the rise in daily LH concentration seen during the follicular phase is associated with an increased amplitude of LH pulses

rather than an increase in LH pulse frequency. This conclusion is based on the observations of LH peak frequency in serum sampling obtained during a 12-hour evening and sleep period in normal women who were studied in either the follicular or the luteal phase of a placebo cycle and a clomiphene citrate cycle. Four women were studied in each arm. They were evaluated on cycle day 9, the last day of administration of clomiphene, and on luteal day 10 after a urinary LH surge. In addition to studying the variety of hormones in the serum, the authors also performed an endometrial biopsy 11 days after the urinary LH surge.

The authors confirmed that there was an increase in the mean peripheral follicular phase LH levels in patients receiving clomiphene citrate and that there was no change in the mean LH levels of patients in the luteal phase; these findings support the concept that the action of clomiphene is primarily in the immediate early follicular phase during and immediately after the clomiphene dose. The authors also confirmed an increase in the mean estradiol level in the follicular and luteal phases and essentially a doubling of the progesterone level in the luteal phase of patients receiving clomiphene citrate. These findings have been previously reported in the literature and would seem to reflect multiple follicle and corpus luteal development in normal women receiving clomiphene.[2] The authors also explored the question as to whether clomiphene citrate might affect luteal phase adequacy on the basis of luteal phase length and endometrial biopsy. They noted no difference between the cycle day of urinary LH rise or the length of the luteal phase. They also demonstrated no histologic evidence of luteal phase deficiency in association with clomiphene treatment. This is an interesting finding in that they have examined eight biopsy specimens, all of which were in phase. The literature suggests that, even in normally ovulating women, approximately 20% of cycles show some endometrial abnormality. However, in this small sampling it is not surprising that this was not detected. Statistical significance would not have been shown, however, had a single abnormal endometrial biopsy specimen been detected in the clomiphene group, because the frequency of the abnormality is sufficiently high in normal cycles as to make it difficult to attribute to the drug.

The major focus of the article has to do with the effect of clomiphene on LH pulsatility. In this regard there are several comments to be made. The first is that there is an unusually high frequency of LH pulses or, stated another way, an extremely low LH interpulse interval reported in this study. Pulses are reported to occur between 30 and 50 minutes in both follicular and luteal phases. This is quite contrary to the literature in which the normal interpulse interval reported is approximately every 90 minutes in the follicular phase and every 2 to 3 hours in the luteal phase. Previous sleep studies have suggested that this pulse frequency actually decreases further during the night by an average of approximately 25 minutes.[3] In sleep, midluteal LH peaks have been reported to be as infrequent as every 5 hours. In the analysis of the LH peaks by the method described, the authors were unable to detect an increased frequency of LH peaks after clomiphene citrate administration, in contrast with other studies. They did, however, note an increase in LH amplitude. Their interpretation is that this eliminates an increase in gonadotropin releasing hormone pulse frequency at the hypothalamic level as a cause of clomiphene activity. It does not, however, rule out an increase in the amplitude of gonadotropin releasing hormone pulses or an increase in the sensitivity of the pituitary to gonadotropin releasing hormone pulses as the cause of clomiphene's action.

Of major import to interpretation of the results is the selection of a computer program for the analysis of the episodic release of LH.[4] A variety of methods have been used in the past to identify LH peaks and there are a number of programs available for performing this analysis. This is an intricate and controversial area of neuroendocrinology, and the selection of the program PULSAR used in this study clearly appears to have had a significant impact on the results.

I have several questions for the authors.

1. Why did they select the evening for performing their studies? Do they feel the nocturnal LH peaks are more important in neuroendocrine function?
2. Did they look at pelvic ultrasonograms to confirm the number of follicles in the patients responding to clomiphene therapy?
3. How did they interpret their endometrial biopsy specimens? The endometrial biopsies were timed on the basis of a midcycle LH peak. However, the analysis of the histologic features is based on time to the subsequent menses. Which method did they use for analysis and was there a discrepancy noted between the two methods of analysis?
4. How did they explain the fact that all of their endometrial biopsy specimens were normal in light of previous studies that detected approximately 20% discrepancy in endometrial biopsy specimens, even in normal women?
5. Have they submitted their LH pulsatility data to analysis by another computer program besides PULSAR? If so, did they get the same results and how do they interpret these very frequent LH peaks that have not been reported previously? Do they feel that these are physiologically significant? Is there a method by which they can analyze their data and report the peak frequencies previously noted by other authors?

Dr. Archer (Closing). I want to thank Dr. Hammond for what I thought was a very penetrating and cogent discussion of this article, touching on the highlights and pointing out some problems that we might have that could be rectified.

First, why we did the study in the evening is unique because we did not start out to look at evening samples in normal menarchal women. Several years ago I became very interested in the fact that some menopausal women wake up between 4 and 5 AM for no apparent reason and stay awake. I thought that some phenomenon occurring at night should be investigated. This was coupled with data regarding a nocturnal, sleep-related LH secretion during puberty, and I felt that these nocturnal LH pulses might be of significance to us in terms of neuroendocrine function. There was also a suggestion that if clomiphene citrate did increase pituitary LH pulses and did so at night as opposed to day, this might be the principal mechanism of action of clomiphene in changing LH secretion. The increased nocturnal LH pulses could result in the pathophysiologic finding of luteal phase defects. Increased follicular stage LH pulse frequency has been reported to occur in women with luteal phase defects.[1]

We are continuing to analyze our data to determine if there is a change in sleep-associated LH pulses. All of these women have been studied in the sleep laboratory with sleep stages determined on a minute-to-minute or second-to-second basis, and those data are now being analyzed with Dr. Ware.

We did have problems with the endometrial biopsies. I must admit that in my enthusiasm for this study we looked at the biopsy specimens from the time of the urinary LH surge to the biopsy date. When the pathologist reported that they were within day 23 to day 25 as I expected them to be, I just assumed that that was right. After we looked again at the data base, three of these eight women have luteal phase lengths of <13 days (one 11, one 12, and one 13). It is conceivable, if we use the criteria of Noyes et al. and the onset of the next menstrual period and then count back and look critically at these biopsy specimens, that we might find one or two that are out of phase. Whether that will be significant I am not sure, but at least it will again indicate to us that clomiphene may have some effect that is picked up histologically.

Last, in terms of an LH pulse analysis program, PULSAR is the program we had readily available to us and we used it. It has some deficiencies. One of the deficiencies that is obvious to us is that it picks up a lot of background noise. We have obtained, from the University of Virginia, Dr. Johannes Veldhuis' program, Cluster Analysis.[2] We have reanalyzed these data by means of Cluster Analysis (Table I).

Luteinizing hormone pulse amplitudes are greater with the Cluster Analysis program than the PULSAR program, since the measurement is from the preceding nadir to peak. PULSAR measures peak amplitudes from a smoothed mean to the apex of the identified peak. The relationship still exists that clomiphene citrate increases mean LH pulse amplitude in the follicular phase. There is no difference in mean LH pulse amplitude in the luteal phase of either clomiphene citrate– or placebo-treated women.

The interpulse interval between clomiphene citrate and placebo is not statistically different in the follicular phase of the cycle on the basis of Cluster Analysis (76 and 89 minutes respectively). This pulse frequency is more in keeping with the published literature of approximately one pituitary LH pulse per hour. This interval is greater (slower) with Cluster Analysis than with

Pulsar. We believe that Cluster Analysis has a more accurate identification of discrete pulses since it takes into account both preceding nadir and postpeak nadirs for pulse identification. Of interest is that the luteal phase interpulse interval is longer with placebo than with clomiphene citrate. This supports our contention that clomiphene citrate persists in the body and continues to have a central effect on hypothalamic function.

A89-A7450T

Demulen® 1/35

(ethynodiol diacetate 1 mg, ethinyl estradiol 35 mcg)

Demulen 1/35™ Each white tablet contains ethynodiol diacetate 1 mg and ethinyl estradiol 35 mcg. Each blue tablet in Demulen 1/35-28 is a placebo containing inert ingredients.

Demulen 1/50™ Each white tablet contains ethynodiol diacetate 1 mg and ethinyl estradiol 50 mcg. Each pink tablet in Demulen 1/50-28 is a placebo containing inert ingredients. **Indication and usage:** For prevention of pregnancy. Pregnancy rate for products with ≥35 mcg ethinyl estradiol or ≥50 mcg mestranol is ≤1/100 woman-years. With ≤35 mcg ethinyl estradiol, rate is slightly higher; with progestogen-only oral contraceptives (OCs), rate is about 3. Precise comparisons cannot be made. Rates for other methods have been published. *Dose-related Thromboembolic Risk*: Studies showed positive association between OC estrogen dose and thromboembolic risk. It is in keeping with good therapeutics to minimize estrogen exposure. Prescribe product containing least amount of estrogen compatible with acceptable pregnancy rate and patient acceptance. Start new users on ≤50 mcg estrogen. **Contraindications:** Thrombophlebitis, thromboembolic disorders, past history of deep vein thrombophlebitis or thromboembolic disorders; cerebrovascular disease, myocardial infarction or coronary artery disease, or past history of these; known or suspected breast carcinoma, estrogen-dependent neoplasia, or pregnancy; undiagnosed abnormal genital bleeding; past or present, benign or malignant liver tumors developing during use of estrogenic products. **Warnings:**

Cigarette-smoking increases risk of serious cardiovascular side effects from OC use. Risk increases with age and heavy smoking (15 or more cigarettes/day) and is quite marked in women over 35. OC users should be strongly advised not to smoke. OCs are associated with increased risk of several serious conditions including venous and arterial thromboembolism, thrombotic and hemorrhagic stroke, myocardial infarction, visual disorders, hepatic tumors, gallbladder disease, hypertension, fetal abnormalities. Practitioners should be familiar with the available information relating to these and other risks.

1. *Thromboembolic disorders and other vascular problems:* Increased risk of thromboembolic and thrombotic disease associated with OCs is well established. A British study showed increased risk for fatal venous thromboembolism (TE). British and U.S. studies showed increased risk for nonfatal disease. U.S. studies showed increased risk for stroke. OC users were 2-11 times more likely to manifest these diseases without evident cause. In a study of idiopathic deep vein thrombosis and pulmonary embolism (PE), projected hospitalization rates for ages 16-40 were 47/year/100,000 users and 5 for nonusers. Overall excess mortality from PE or stroke was 1.3-3.4 deaths/year/100,000 users and increased with age. *Cerebrovascular Disorders:* In a study of stroke with and without predispositions, risk of hemorrhagic stroke was 2 times greater and thrombotic stroke 4.0-9.5 times greater in users. Mortality trends in 21 countries indicate that changes in cardiovascular mortality were associated with changes in OC prevalence. The Royal College of GPs (RCGP) reported on its prospective study: "A statistically significant higher rate of reporting of cerebrovascular accidents in Takers is evident, but the numbers are too small to justify an estimation of the degree of risk." A 1981 analysis showed a 4-fold increased mortality in users from circulatory diseases, mainly myocardial infarction (MI) and hemorrhagic stroke. Excess mortality was associated with age and smoking. A 1983 analysis showed elevated cerebrovascular disease, increasing with use to 8 yrs, including cerebral thrombosis or embolism and TIA. Peripheral arterial disease and MI were increased. Women over 30 had more arterial disease, being greatest in smokers. Arterial case-fatality was 2-3 times greater for users who smoked. Family Planning Assoc. (FPA) found significant association between OC use and stroke; increased risk for venous thrombosis and PE was 4-fold and statistically significant. Mortality from nonrheumatic heart disease was greater in ever-users. In the Walnut Creek Study, subarachnoid hemorrhage risk was associated with smoking, age, and OC use. *Myocardial Infarction:* Increased risk of MI associated with OCs was reported in Britain, as previously suspected. The morbidity study found the greater the number of risk factors for coronary artery disease (smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk, regardless of OC use. OCs were an additional risk factor. Excess rate of fatal MI was 3.5/year/100,000 users aged 30-39 and 20 for ages 40-44. (These are based on British statistics with acute MI death rates 2-3 times less than the U.S. Similar estimates for the U.S. are 25.7 for users aged 30-39 with predispositions vs 1.5 without; for ages 40-44, 86.2 vs 5.1.) Excess hospitalization rate for nonfatal MI in Britain was 3.5/year/100,000 users aged 30-39 and 47 for ages 40-44. Smoking major predisposing condition to MI. In terms of relative risk, nonsmoking OC users are twice as likely to have fatal MI as nonsmoking nonusers. Smoking users have a 5-fold greater risk than nonsmoking users, but a 10-12-fold greater risk than nonsmoking nonusers. Amount of smoking is an important factor. In determining importance of these risks, give serious consideration to rates in table below. Importance of other predispositions cited above in determining relative and absolute risks has not been quantified; it is likely the same synergism exists, but perhaps to a lesser extent. U.S. studies similarly relate MI, OCs, smoking, and age.

Estimated Mortality Rate from Myocardial Infarction per 100,000 Women/Year

	Aged 30-39:	*Users*	*Nonusers*	*Aged 40-44:*	*Users*	*Nonusers*
All smokers		10.2	2.6		62.0	15.9
≥15 cigarettes daily		13.0	5.1		78.7	31.3
<15 cigarettes daily		4.7	0.9		28.6	5.7
Nonsmokers		1.8	1.2		10.7	7.4
Smokers and nonsmokers		5.4	1.9		32.8	11.7

Risk of Dose: Reports of TE after use of OCs with ≥50 mcg estrogen received by drug safety committees in Britain, Sweden, and Denmark were compared with distribution expected from market research sales estimates. A positive correlation was found between estrogen dose and reporting of TE, including coronary thrombosis, in excess of that predicted by sales. OCs with ≥100 mcg estrogen were associated with higher TE risk than those with 50-80 mcg. Estrogen quantity may not be the sole factor; influence of progestogens was not considered, which may be responsible for certain discrepancies in the data. No significant differences were noted between OCs containing same estrogen dose nor between ethinyl estradiol and mestranol. In Britain certain TE conditions were associated with progestogen or estrogen dose. In Sweden reports of TE decreased when higher estrogen doses were no longer prescribed. Studies on TE risk with progestogen-only OCs have not been done. Cases have been reported for these; they are not presumed free of risk. In a U.S. case-controlled study, relative risk of OC use 1 month before hospitalization for various types of TE was calculated. If relative estrogenic potency and possible influence of different progestogens are ignored, OCs may be divided into those with <100 mcg and those with ≥100 mcg estrogen. For all cases combined, larger doses were associated with only slightly higher risk; for idiopathic cases risk was doubled with larger doses, but confidence limits overlapped and differences were not significant. Apparently there was less increased risk for cases with predispositions. In FPA study no nonhemorrhagic strokes occurred with <50 mcg estrogen, vs 13 with higher doses. TE risk in users and nonusers increases with age. OCs have been considered an independent risk factor. *Persistence of Risk* after OC discontinuation was reported for circulatory disease, nonrheumatic heart disease, and cerebrovascular disease, including subarachnoid hemorrhage, cerebral thrombosis, and TIA. *Excess Mortality from Circulatory Diseases:* A U.K. prospective study estimated annual mortality from circulatory diseases for OC users and nonusers by age, smoking, and duration of use. Excess mortality was 23/100,000 users (2 and 10 for ages 25-34, 15 and 48 for ages 35-44, 41 and 179 for ages >44, for nonsmokers and smokers, respectively). Risk was significant only for smokers over 34. Most deaths were due to subarachnoid hemorrhage or ischemic heart disease. Risk for ever-users rose with parity. One study estimated risk of death with various contraceptive methods, each estimate including risk of method (eg, TE for OCs) plus risk due to pregnancy or abortion in cases of method failure. This latter risk varies with effectiveness. It concluded mortality with all methods is low and below that of childbirth, except for OC users over 40 who smoke. Heavy smokers have double the risk of smokers, light smokers about half. Mortality with OC use in nonsmokers over 40 is higher than with any other method in that age group. Lowest mortality is with condom or diaphragm backed up by early abortion. Risk of TE and thrombotic disease with OCs increases with age after 30 and, for MI, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia, and especially cigarette smoking. Based on current data, the chart gives gross estimates of risk of death from circulatory disorders associated with OCs:

Risk is: A—very high; B—high; C—moderate; D—low. Age:	<30	30-39	≥40
Heavy smokers (≥15/day)	C	B	A
Light smokers (<15/day)	D	C	B
Nonsmokers, no predispositions	D	C,D	C
Nonsmokers, with predispositions	C	C,B	B,A

Be alert to earliest manifestations of TE and thrombotic disorders (eg, thrombophlebitis, PE, cerebrovascular insufficiency, coronary artery disease, MI, retinal thrombosis, mesenteric thrombosis). Should any be suspected, discontinue OCs immediately. A 4-7-fold increased risk of postsurgery TE was reported in users; if feasible discontinue OCs at least 4 weeks before surgery or in prolonged immobilization. Before resuming OCs, weigh risks of postsurgery TE complications against contraceptive needs. The RCGP prospective study reported higher incidence of superficial and deep vein thrombosis in users, the former correlated with progestogen dose. The data suggest varicose veins have little effect on development of deep vein thrombosis but substantially increase risk of superficial vein thrombosis, risk depending on severity of varicosities. **2.** *Ocular lesions:* Neuro-ocular lesions such as optic neuritis or retinal thrombosis have been associated with OCs. Discontinue if there is unexplained, gradual or sudden, partial or complete loss of vision; proptosis or diplopia; papilledema; or evidence of retinal vascular lesions. Institute diagnostic and therapeutic measures. **3.** *Carcinoma:* Long-term estrogen in certain animals increases carcinomas and/or nonmalignant neoplasms, such as those of breast, uterus, cervix, vagina, ovary, liver, pituitary. Some synthetic progestogens, none currently in OCs, increase incidence of benign and malignant mammary nodules in dogs. There is evidence that estrogens increase risk of human endometrial carcinoma. In case-controlled studies, increased risk (2.2-13.9 times) associated endometrial carcinoma with prolonged estrogen for menopausal symptoms. Risk was independent of other known risk factors and depended on duration of use and dose. This is supported by increased endometrial cancer incidence since 1969 in areas with cancer-reporting systems, which may be related to rapidly expanding estrogen use. There is no evidence that natural estrogens are more or less hazardous than synthetics at equi-estrogenic doses. Of the first 30 cases endometrial carcinoma in OC users under 40, those without predispositions (eg, irregular bleeding before OCs, polycy ovaries) occurred nearly always with no-longer-marketed sequential OCs. No statistical association is reported suggest increased endometrial cancer with combination or progestogen-only OCs, though individual cases were reported. Studies sh no increased breast cancer with OCs or estrogens. However, greater risk was noted in OC users with benign breast dise or long-term (2-4 years) use. One study found greater risk of breast cancer with >4 years OC use prior to first full-te pregnancy. Risk of breast cancer with menopausal estrogens rose and further increased with duration of follow-up. OCs estrogen were related to breast cancer in connection with other risk factors. Decrease in benign breast tumors in OC users well known. Some studies suggested increased risk of cervical dysplasia, erosion, and carcinoma in long-term users. Cervi microglandular hyperplasia has been reported. In summary, there is no consistent evidence from human studies of increas cancer risk with OCs. Close surveillance is, however, essential. In undiagnosed persistent or recurrent abnormal vagi bleeding, consider nonfunctional causes and take diagnostic measures to rule out malignancy. Carefully monitor users w strong family history of breast cancer or with breast nodules, fibrocystic disease, recurrent cystic mastitis, abnorm mammograms, or cervical dysplasia. **4.** *Hepatic adenomas, etc,* have been associated with OCs. In 1 study OC formulatic with high "hormonal potency" were associated with higher risk, as was age over 30. Though benign, these lesions m rupture and cause fatal hemoperitoneum in short- or long-term users. Two studies related risk to duration of use, being mu greater after ≥4 years. Long-term OC users have an estimated adenoma incidence of 3-4/year/100,000. Consider su lesions in users with abdominal pain, tenderness, mass, or shock. About 25% present with abdominal masses, up to h with acute hemoperitoneum. Radiologic and lab studies may not be helpful; liver scans may show local defect. Hepa arteriography or CAT may be useful. Hepatocellular carcinoma risk is increased 7-20 times in users for 8 or more years. B duct cancer may occur with OC use. OCs are contraindicated in case of past or present, benign or malignant liver tumc developing during use of estrogenic products. **5.** *Use in or immediately preceding pregnancy, birth defects, malignancy offspring:* Estrogens or progestogens during early pregnancy may seriously damage offspring. Females exposed in utero DES and other nonsteroidal estrogens may have increased risk of vaginal or cervical cancer. Though OCs may not enhan this risk, monitor such patients carefully. From 30-90% of DES-exposed women develop benign vaginal or cervical adenos which could be premalignant. DES-exposed daughters have more unfavorable pregnancy outcomes. Males so exposed m develop urogenital and sperm defects. Other estrogens may mimic DES. Reports relate fetal exposure to female sex hormon and congenital anomalies, eg, VACTERL for vertebral, anal, cardiac, tracheoesophageal, renal, and limb defects. There appea preferential expression by males. There was a 4.7-fold increased risk of limb-reduction defects in infants exposed in utero sex hormones (OCs, hormonal withdrawal pregnancy tests, or treatment for threatened abortion). Some exposures were ve short, being only a few days. Cardiovascular defects in children exposed to female hormones, including OCs, during ea pregnancy occurred in 18.2/1,000 births, compared to 7.8 for those unexposed (P<.05). More twinning was reported conceptions shortly after OC discontinuance. Female sex hormones were used for threatened or habitual abortion, but the is considerable evidence estrogens are ineffective and no evidence progestogens are effective. Triploidy and possibly oth polyploidy may be increased in abortuses from women becoming pregnant soon post-OC. These almost always abc spontaneously. It is unknown if spontaneous abortion is increased soon after stopping OCs. Increased chromosome aberratio have been reported. Safety of OCs in pregnancy has not been demonstrated. Rule out pregnancy in using OCs and alway consider it if withdrawal bleeding does not occur. If 2 consecutive periods are missed rule out pregnancy before continuin If user deviates from regimen, consider pregnancy at first missed period and withhold OCs. If pregnancy is confirmed, appris patient of potential fetal risks and discuss continuation of pregnancy. Users discontinuing for pregnancy should use alternati contraception for 3 months before attempting to conceive, though this is not based on precise information. Do not us progestogen-only or progestogen-estrogen drugs as pregnancy tests. **6.** *Gallbladder disease* risk, surgically confirme appeared after 2 years' use and doubled after 4-5 years in 1 study; it appeared in 6-12 months' use in another. **7.** *Carbohydra and lipid metabolism:* Decreased glucose tolerance occurs in a significant number of users; carefully observe diabetic an prediabetic patients. Triglycerides, total phospholipids, and lipoproteins may increase. **8.** *Elevated blood pressure* (BP) occu in some users in a few months, and degree may relate to progestogen dose. Hypertension prevalence in users is not highe in the first year, but increases with longer exposure; in the 5th year it is 2½—3 times the first year. Age is strongly correlate with hypertension in users. Those with history of elevated BP (hypertension), preexisting renal disease, history of toxemia elevated BP in pregnancy, familial tendency to hypertension or its consequences, or history of excessive weight gain or flu retention during menstrual cycles may be more likely to develop elevated BP on OCs and should be monitored closely. Eve though elevated BP may be in "normal" range, do not ignore implications. Follow closely, particularly those with other ris factors for cardiovascular disease or stroke. High BP may or may not persist after stopping OCs. **9.** *Headache:* Onset exacerbation of migraine or development of headache of a new pattern that is recurrent, persistent, or severe requires stoppir OCs and evaluating cause. **10.** *Bleeding irregularities:* Breakthrough bleeding (BTB), spotting, and amenorrhea are freque reasons for discontinuing. In BTB, as in all cases of irregular bleeding, consider nonfunctional causes. In undiagnose persistent or recurrent bleeding, rule out pregnancy or malignancy. If pathology is excluded, time or change to another produ may suffice. Change to a higher-estrogen OC only when necessary as this may increase thromboembolic risk. Those wit history of oligomenorrhea or secondary amenorrhea or without established regular cycles may be anovulatory or amenorrhe after discontinuing. Those with such problems should be so informed and other methods encouraged. Post-use anovulatio possibly prolonged, may occur in women without previous irregularities. Higher incidence of galactorrhea and of pituitar tumors has been associated with postpill amenorrhea. One study reported 16-fold increased prevalence of pituitary prolactir secreting tumors in patients with postpill amenorrhea when galactorrhea was present. **11.** *Ectopics:* In failures with combinatio OCs, the ratio of ectopic to intrauterine pregnancies is no higher than in nonusers. There may be increased risk of ectopic after discontinuing. **12.** *Breast feeding:* OCs may decrease quantity and quality of milk. A small fraction of OC steroids appear in milk. Effects if any on child are unknown. If feasible defer OCs until after weaning. **13.** *Infertility* may occur after discontinuin OCs. While impairment diminishes with time, there is still an appreciable difference in nulliparas aged 25-29 after 30 months difference is negligible after 48 months. In nullips aged 30-34 impairment persists to 72 months and is more severe for 2 year users. In paras aged 25-34, difference is negligible after 30 months. **Precautions:** Conduct complete history and physica prior to OC use and annually thereafter. Include breasts, abdomen, and pelvis, with BP, Pap, and lab tests. Preexisting uterin leiomyomata may enlarge. Mental depression may occur; with positive history, observe carefully and discontinue if seriou recurrence. Fluid retention may occur; prescribe cautiously and monitor carefully in convulsive disorders, migraine, asthma or cardiac, hepatic, or renal dysfunction. History of jaundice in pregnancy increases risk of recurrence on OCs; observ carefully and discontinue if it occurs. Cholestatic jaundice occurred after OC and troleandomycin use. OC/cyclosporin combination may be hepatotoxic. Steroids may be poorly metabolized in liver dysfunction and should be given cautiously Tryptophan metabolism may be disturbed and result in pyridoxine deficiency; megaloblastic anemia has been reported. Serun folate may be depressed and may be exacerbated in post-OC pregnancy. Advise pathologist of OC use when submittin specimens. Endocrine and liver function tests may be altered; repeat abnormal tests after stopping for 2 months. These hav been observed: increased BSP retention and other abnormalities in liver function tests; increased prothrombin and coagulatio factors VII, VIII, IX, X; decreased antithrombin III, increased platelet aggregability; increased thyroid-binding globulin leadin to increased circulating total thyroid hormone (PBI, T_4); decreased T_3 uptake, unaltered free T_4, decreased pregnanedic excretion; reduced metyrapone response; increased blood transcortin, corticosteroid, triglyceride, phospholipid, reduced serun folate; impaired glucose tolerance; altered plasma trace minerals. Influence of prolonged OC use on pituitary, ovarian, adrenal hepatic, or uterine function, or on immune response not established. OCs may mask onset of climacteric. Cervical chlamydia prevalence is increased; do not assume OC protects against chlamydial PID. *Information for patients.* See patient labeling *Drug interactions.* OC effectiveness may be decreased and more BTB occur with rifampin, isoniazid, ampicillin, neomycin penicillin V, tetracycline, chloramphenicol, sulfonamides, nitrofurantoin, griseofulvin, barbiturates, phenytoin, carbamazepine primidone, phenylbutazone, analgesics, tranquilizers, antimigraines. OCs may alter effectiveness of oral anticoagulants anticonvulsants, tranquilizers, tricyclic antidepressants, antihypertensives, theophylline, caffeine, vitamins, hypoglycemics, clofibrate, glucocorticoids, acetaminophen. **Adverse reactions:** Increased risk of the following serious adverse reactions has been associated with OCs: thrombophlebitis and thrombosis; pulmonary embolism; arterial thromboembolism; Raynaud's disease, myocardial infarction; coronary thrombosis; cerebral thrombosis; cerebral hemorrhage; hypertension; gallbladder disease; Budd-Chiari syndrome; benign adenomas and other hepatic lesions, with or without intra-abdominal bleeding, liver cancer, congenital abnormalities. There is evidence of association between the following and OCs, though confirmatory studies have not been done: mesenteric thrombosis; neuro-ocular lesions, eg, retinal thrombosis and optic neuritis. The following are believed drug related: nausea, vomiting, gastrointestinal symptoms, BTB, spotting, change in menstrual flow, dysmenorrhea, amenorrhea during and after use, infertility post-OC, edema, chloasma or melasma, which may persist post-OC, breast changes (tenderness, enlargement, secretion), weight changes, change in cervical erosion and secretion, endocervical hyperplasia, lactation decrease, cholestatic jaundice, migraine, enlarged uterine leiomyomata, allergic rash, mental depression, reduced carbohydrate tolerance, vaginal candidiasis, change in corneal curvature (steepening), intolerance to contact lenses. Association not confirmed or refuted for: premenstrual-like syndrome, cataracts, libido changes, chorea, appetite changes, cystitis-like syndrome, headache, paresthesia, nervousness, dizziness, auditory disturbances, rhinitis, fatigue, backache, hirsutism, scalp hair loss, erythema multiforme or nodosum, hemorrhagic eruption, herpes gestationis, hemolytic uremia, malignant hypertension, itching, vaginitis, porphyria, impaired renal function, acute renal failure, sometimes irreversible, PVCs, abnormal EKG, pulmonary hypertension, TTP, anemia, pancreatitis, hepatitis, colitis, Crohn's disease, gingivitis, dry socket, lupus erythematosus, rheumatoid arthritis, pituitary tumors (eg, adenoma) with amenorrhea and/or galactorrhea after use, malignant melanoma, endometrial, cervical, breast, and bile duct carcinoma. **Acute overdosage:** Serious ill effects have not been reported after large acute doses of OCs in young children. Nausea and withdrawal bleeding might occur. **Important note: Complete prescribing information should be consulted prior to use and is available on request.**

Operative Gynecologic Endoscopy

edited by **Joseph S. Sanfilippo** and **Ronald L. Levine**

Operative Gynecologic Endoscopy is a clinically oriented text that covers both the theory and practice of basic to advanced endoscopic techniques. Noted authorities carefully detail procedures for operative endoscopy, laser laparoscopy, operative hysteroscopy, and laser hysteroscopy.

Only *Operative Gynecologic Endoscopy* covers the aspects of gynecologic endoscopy unique to practice in North America. Contributors to the volume are well-known clinicians and scientists from 24 leading North American institutions. They are the people who have pioneered the use of endoscopy to improve the healthcare of gynecologic patients.

Learn the best approach. The authors help you to decide which approach is best suited to a wide range of gynecologic pathologies and conditions, including ectopic pregnancy, pelvic inflammatory disease, ovarian cysts, infertility, and endometriosis.

Plus — An insightful history by Kurt Semm . . . How to choose the right equipment . . . Description of photographic equipment and techniques including video . . . Safety precautions and basic trouble-shooting methods . . . The role of operating room personnel . . . Medico-legal aspects . . . Economic impact . . . Credentialing and the future of gynecologic endoscopy.

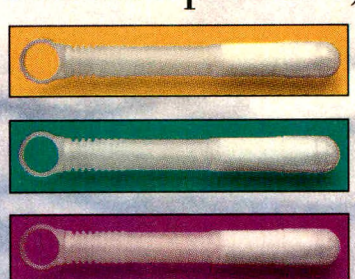
Make a clean break

to 3-day therapy*

Cure vulvovaginal candidiasis in just three days*

Broad spectrum of activity

- Cures infections due to *Candida albicans* and *Candida tropicalis* within 3 days.



Documented 3-day efficacy

- Microbiological cure rates of 95% eight days following Femstat 3-day therapy.[1]
- Low relapse rates 30 days post therapy.

Femstat Prefill is:

- NOT a triazole/NO flu-like symptoms.
- Safe in second- and third-trimester pregnant patients.*

Patented prefilled, disposable applicators

- Disposable to reduce risk of reinfection.
- Prefilled for unit-dose accuracy.
- Designed for enhanced patient compliance.

*In pregnant patients (second and third trimesters only), therapy should be extended to six days.

vaginal cream 2%

Femstat® Prefill

(butoconazole nitrate)

™

Make it your choice for unsurpassed efficacy and convenience.

vaginal cream 2%

Femstat® Prefill

(butoconazole nitrate)

BRIEF SUMMARY

INDICATIONS: FEMSTAT® (butoconazole nitrate) vaginal cream 2.0% is indicated for local treatment of vulvovaginal mycotic infections caused by Candida species. Confirm the diagnosis by KOH smears and/or cultures. FEMSTAT can be used with oral contraceptives and antibiotics. It is effective in non-pregnant women and during the second and third trimesters of pregnancy.

CONTRAINDICATIONS: FEMSTAT is contraindicated in patients hypersensitive to any of the ingredients.

PRECAUTIONS: General: If clinical symptoms persist, repeat microbiological tests to rule out other pathogens and confirm the diagnosis. Discontinue drug if sensitization or irritation occurs.

Information for the Patient: Do not discontinue prematurely during menstruation or because of symptomatic relief.

Carcinogenesis: Animal studies have not been done.

Mutagenesis: Mutagenicity studies were negative.

Impairment of Fertility: Animal studies showed no impairment of fertility.

Pregnancy Category C: Adverse effects were noted in animals treated with high oral doses. No studies were done in women during first trimester. Patients in the second or third trimester have shown no adverse effects attributable to the drug.

Nursing Mothers: Use with caution.

Pediatric Use: Safety and efficacy have not been established.

ADVERSE REACTIONS: Vulvar/vaginal burning in 2.3% of patients, vulvar itching in 0.9%, discharge, soreness, swelling, itching of fingers each in 0.2%. Complaints caused 1.6% to discontinue drug.

DOSAGE AND ADMINISTRATION:
Non-pregnant Patients: The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for three days. Treatment can be extended for an additional three days if necessary.

Pregnant Patients (second and third trimesters only): The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for six days.

CAUTION:
Federal law prohibits dispensing without prescription.

TRANSACTIONS OF THE NINTH ANNUAL MEETING OF THE SOCIETY OF PERINATAL OBSTETRICIANS

Management of women with one abnormal oral glucose tolerance test value reduces adverse outcome in pregnancy

Oded Langer, MD, Akolisa Anyaegbunam, MD, Lois Brustman, MD, and Michael Divon, MD

Bronx, New York

In this study we sought to test the hypothesis that treatment of women with one abnormal oral glucose tolerance test value will result in reduction of adverse outcome. One hundred twenty-six women with one abnormal oral glucose tolerance test value and 146 women in the control group (normal oral glucose tolerance test values) participated in a prospective study during the third trimester of pregnancy. The subjects with one abnormal test result were randomized into treated (group 1) and untreated groups (group II). Group 1 subjects were treated with a strict diabetic protocol to maintain tight glycemic control by means of diet and insulin therapy. Group 2 subjects tested their capillary blood glucose for a baseline period. The study revealed that the level of glycemic control was similar before initiation of therapy (mean capillary blood glucose 118 ± 14 vs. 119 ± 15 mg/dl, p = NS) for groups 1 and 2, respectively. There was a significant difference in mean capillary blood glucose (95 ± 10 vs. 119 ± 15 mg/dl, $p < 0.0001$), preprandial, and postprandial determinations between the treated and untreated groups. The overall incidence of neonatal metabolic complications (4% vs. 14%, $p < 0.05$) and large infants (6% vs. 24%, $p < 0.03$) was significantly lower in the treated group. Comparison between the control (normal oral glucose tolerance test) and the untreated groups showed a significantly higher incidence of large infants and metabolic complications. No difference was found between the normal and treated groups. Thus we conclude that treatment of individuals with one abnormal oral glucose tolerance test value will result in significant reduction in adverse outcome in pregnancy. (Am J Obstet Gynecol 1989;161:593-9.)

Key words: Treatment, oral glucose tolerance test, one abnormal value, pregnancy outcome

Controversy exists with regard to the precise criteria for diagnosis of gestational diabetes mellitus. The most accepted forms are the World Health Organization criteria in Europe and the National Diabetes Data Group in the United States, which were recognized at two international gestational diabetes conference workshops in 1979 and 1984.[1, 2] At least two values on the oral glucose tolerance test (GTT) must be abnormal to diagnose gestational diabetes mellitus. Previously we tested the hypothesis that women with one abnormal oral GTT value are at higher risk for adverse outcome in pregnancy. It was demonstrated that these women are metabolically (glucose levels) similar to patients with gestational diabetes (NDDG). In addition, the group with one abnormal test result had a high incidence of neonatal morbidity (mainly macrosomia and metabolic complications).[3] Recently our finding of an increased risk of fetal macrosomia in patients with one abnormal value on their oral GTT results was confirmed by other investigators.[4] Thus these women are the closest "model" for untreated gestational diabetics diagnosed by the National Diabetes Data Group criteria. In this study we sought to test the hypothesis that treatment of women with one abnormal value (oral GTT) will result in reduction of adverse outcome.

Three objectives were identified to initiate investi-

Previous stillbirth (% and No.)	5 (3)	5 (3)	2 (3)	NS

LGA, Large-for-gestational-age.
*Group 1 versus groups 2 and 3.

gation of this hypothesis: (1) to determine the glycemic profile in treated and untreated women with one abnormal value, (2) to ascertain the relationship between maternal and neonatal outcome in untreated and treated women with one abnormal value, and (3) to compare pregnancy outcome in normal women and women with one abnormal value.

Material and methods

Identification of study population. At our medical center all pregnant women are routinely screened for gestational diabetes between 24 and 28 weeks' gestation. Screening consists of a 50 gm oral glucose load. If the 1-hour plasma glucose value is ≥130 mg/dl, the patient is scheduled for a full 3-hour oral GTT. To assure consistency in testing procedure, all women are instructed to add 150 gm of carbohydrate to their usual meals for each of 3 days before the oral GTT. Interpretation of oral GTT results was made in accordance with the criteria established by the National Diabetes Data Group.[5] Patients are instructed to fast for 12 hours (overnight) before the test. The test is initiated between 8:30 and 9:00 AM.

Study design. Two hundred seventy-two women participated in this prospective study during the third trimester of pregnancy. The study group consisted of 126 patients with one abnormal value on their oral GTT. Written and informed consents were obtained from all subjects. They were randomized into treated (group 1) and untreated (group 2) groups. For the purpose of the study, women with screening results of <140 mg/dl (which are considered normal screening results according to the National Diabetes Data Group and the American College of Obstetricians and Gynecologists technical bulletin No. 92, May 1986) and normal oral GTT (all normal values) served as the control (group 3).

Blood glucose evaluation. All women with one abnormal value monitored their capillary blood glucose seven times a day with a memory-based reflectance meter to ascertain accurate and reliable data. Group 1 (treated subjects) was assigned to treatment modality in accordance with our diabetic management protocol. Briefly, diet treatment was determined by consideration of body mass index before pregnancy. For obese patients (defined as body mass index ≥27) 25 kcal/kg and for nonobese (body mass index <27) subjects, 30 kcal/kg was prescribed.

The insulin dose was calculated based on 0.7 U of insulin per kilogram of body weight measured in pregnancy. Human insulin was administered by multiple insulin injection regimen. The standard formula for the amount of insulin prescribed was two thirds of all insulin in the morning (2:1, intermediate-acting/regular insulin) and one third in the evening (1:1, regular/intermediate-acting). All subjects were treated with a strict diabetic protocol to maintain tight glycemic control (95 mg/dl). When diet therapy could not achieve this goal, insulin therapy was initiated.[6,7] Group 2 (untreated) subjects were instructed to continue their habitual eating patterns. They also were required to test their capillary blood glucose for a baseline period of 4 weeks.

Outcome evaluation criteria

Maternal. Selected variables (e.g., age, obesity, hypertensive disorder) associated with large infants were evaluated. Hypertensive disorders included pregnancy-induced hypertension and chronic hypertension. Pregnancy-induced hypertension was diagnosed by the presence of proteinuria (>0.5 gm/24 hr), blood pressure >140/90 mm Hg or mean arterial pressure >104 mm Hg. Chronic hypertension was defined as blood pressure >140/90 mm Hg on two separate occasions 6 hours apart, mean arterial pressure >104 mm Hg during the first trimester, or both. The cesarean section rate between the groups was compared.

Table II. Oral GTT result

	Group 1: Treated (n = 63)	*Untreated (n = 63)*	*Control (n = 146)*	*p*
Screening result (mean ± SD)	157 ± 21	150 ± 16	121 ± 15*	<0.0001
Oral GTT result (mg/dl)				
Fasting	93 ± 8	90 ± 11	86 ± 9	<0.0001
1 hr	185 ± 16	181 ± 28	148 ± 25	<0.0001
2 hr	156 ± 18	157 ± 18	123 ± 23	<0.0001
3 hr	116 ± 25	111 ± 26	107 ± 24	NS

Table III. Ambulatory glycemic profile before and after initiation of treatment

	Group 1: Treated (n = 63)		
	Baseline period only	*In treatment*	*Group 2: Untreated (n = 63) (baseline period only)*
Basline period (no. of days)	12 ± 6	73 ± 8	20 ± 6
Fasting (mg/dl)	100 ± 11	84 ± 9*	102 ± 12
Preprandial (mg/dl)	103 ± 11	86 ± 9*	105 ± 12
Postprandial (mg/dl)	130 ± 13	106 ± 10*	131 ± 13
Mean capillary blood glucose (mg/dl)	118 ± 14	95 ± 10*	119 ± 15

*$p < 0.0001$, baseline period versus in treatment.

Neonatal. Infants were considered large for gestational age if their birth weights were ≥ the 90th percentile and small for gestational age when their birth weights were ≤ the 10th percentile for a given gestational age.[8]

Hypoglycemia was defined as blood glucose <35 mg/dl,[9] and was evaluated in all study patients in the delivery room by Dextrostix. Low blood glucose levels were confirmed in the laboratory by the glucose oxidase method. Infants of women in the control group were tested only for symptoms of hypoglycemia. Other metabolic abnormalities included hyperbilirubinemia (bilirubin >12 mg/dl), hypocalcemia (calcium <7.5 mg/dl), and polycythemia (central venous hematocrit >65%). Admissions to the neonatal intensive care unit exceeding 24 hours and cases of respiratory distress syndrome were recorded.

Method of analysis. For purposes of analysis, data on the patients with one abnormal value were divided into two periods: period 1 (baseline before treatment) and period 2 (from initiation of treatment to delivery). Further analysis compared pregnancy outcome between the three groups. Categorical data were evaluated with χ^2 analysis and Fisher's exact test; continuous data were analyzed with Student's *t* test. Pearson's correlation coefficient was calculated for the relationships between level of glycemia and neonatal weight (birth percentile).

Results

Patient characteristics. During the 1-year study period, 3560 women underwent glucose screening; 2919 (82%) had normal results. Of the remaining 641 women with abnormal screening results, 93 had gestational diabetes, 126 had one abnormal value (groups 1 and 2), and 422 had normal oral GTT results. Of the latter group, 146 women had screening results <140 mg/dl (group 3, control). As shown in Table I, no significant difference in maternal age was found between the untreated and control groups. The treated patients were significantly older than the former two groups ($p < 0.005$). In this group, 65% (41 of 63) were diet-treated and 35% (22 of 63) required insulin therapy to achieve good glycemic control. A comparison of selected maternal characteristics of the three groups included race, parity, obesity, gestational age at screening and diagnosis, and revealed no statistically significant differences. In contrast, the subjects with one abnormal test result (groups 1 and 2) had an approximately fivefold greater history of previous macrosomia ($p < 0.009$) and a twofold higher incidence of previous stillbirth ($p < 0.01$).

Screening and oral GTT results. The screening and oral GTT results of group 3 women were significantly lower than those of groups 1 and 2. No difference was found between groups 1 and 2 (Table II). Within groups 1 and 2 the proportion of women with one abnormal value was 6% at fasting, 49% at 1 hour, 27% at 2 hours, and 10% at 3 hours.

Ambulatory glycemic profile

Period I. Table III shows the level of glycemia during the baseline period before initiation of treatment between groups 1 and 2. No significant difference was found in capillary mean blood glucose between the groups. In general, the postprandial values were higher

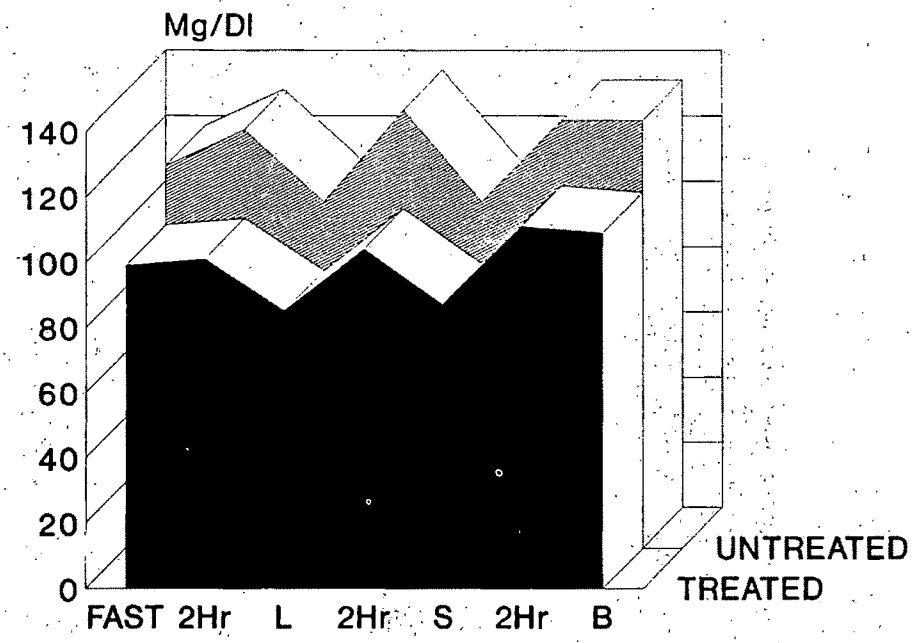

Fig. 1. Ambulatory level of glycemia after initiation of treatment. *L*, Lunch; *S*, supper; *B*, bedtime; *2Hr*, postprandial.

than the preprandial values, with an overall mean for the individuals with one abnormal test result of 119 ± 15 mg/dl.

Period II. Evaluation of ambulatory glycemic profile in group 2 before and after initiation of treatment is displayed in Fig. 1. The analysis revealed that the mean blood glucose level decreased significantly after treatment initiation. The fasting capillary blood glucose level was 102 ± 12 mg/dl before treatment and reduced significantly after treatment (84 ± 9 mg/dl).

Further evaluation comparing the mean blood glucose before and after treatment for the preprandial and postprandial determinations demonstrated significant reduction in blood glucose values (Table III).

Pregnancy outcome. A summary of maternal and neonatal pregnancy outcome appears in Table IV. Overall, 93% of the patients were delivered after 37 weeks, with no significant difference in the rate of prematurity between the groups. From all the selected maternal complications that were analyzed, the only significant difference was found in maternal weight gain between group 2 and the other two groups. In contrast, the weight change in the treated and the control individuals was similar. Infants were similar with respect to gestational age at delivery, with a mean of 39 weeks for all patients. The mean birth weights for the three groups were similar, but for group 1 a 161 gm difference in mean weight was found when compared with the untreated group. This difference was marginally significant ($p = 0.06$). Respiratory distress syndrome was documented for only 3.2% of all neonates, reflecting a range of 3% to 5% for the three groups. The overall incidence for metabolic complication was significantly higher in group 2 when compared with groups 1 and 2 (3% vs. 13%, $p < 0.04$). Hyperbilirubinemia was documented in 15% of group 2 and in approximately 5% of group 1 and 3 subjects. In group 2, polycythemia affected 14% of the neonates; hypoglycemia occurred in 12%. These findings were significantly higher in comparison to the other groups.

The incidence of large infants is displayed in Fig. 2. Significantly fewer appropriate-for-gestational-age infants were delivered of patients from group 2 compared with group 1 or 3. Of the total large-for-gestational-age infants, 82% were macrosomic infants with a similar proportion for each of the three groups.

Additional analysis (Mantel-Haenszel test) of the data was done to determine the relative risk between the groups. The relative risk for large-for-gestational-age infants between groups 1 and 2 was 4.61 (95% confidence interval, 1.44 to 14.81). Comparison between the untreated (group 2) and control (group 3) showed a relative risk of 2.22 (95% confidence interval, 1.04 to 4.76). There was no significant relative risk for large-for-gestational-age infants between the control and the treated groups.

The relationship between maternal obesity and large infants is displayed in Fig. 3. When obese and nonobese mothers were compared within each group, no significant difference was found in the incidence of large infants. However, obese women in the untreated group had a relative risk of 9.1 in comparison with obese

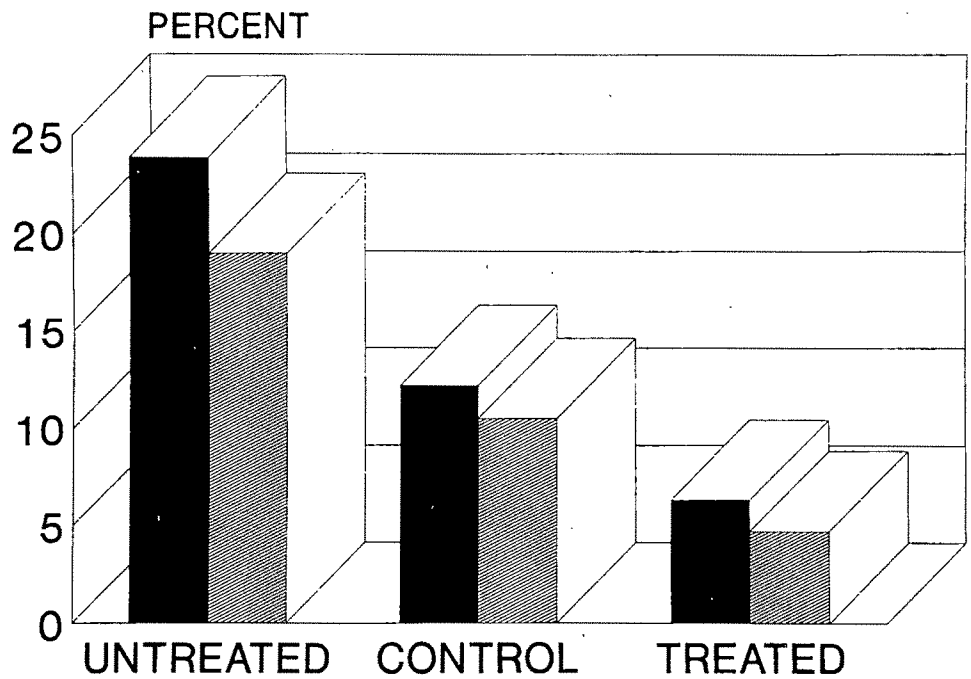

Fig. 2. Association between overall incidence of LGA infants *(darkened area)* and macrosomic *(shaded area)* infants among three groups.

Table IV. Pregnancy outcome

	Group 1: Treated (n = 63)	*Group 2: Untreated (n = 63)*	*Group 3: Control (n = 146)*	*p*
Maternal				
Gestational age at delivery (wk)	39 ± 2	39 ± 1	40 ± 2	NS
Weight gain (kg)	13 ± 4	15 ± 6*	13 ± 6	<0.03
Primary cesarean section (% and No.)	10 (6)	11 (7)	12 (18)	NS
Repeat cesarean section (% and No.)	5 (3)	6 (4)	6 (9)	NS
Hypertensive disorder (% and No.)	3 (2)	5 (3)	7 (10)	NS
Neonatal				
Birth weight (gm) (mean ± SD)	3261 ± 496	3422 ± 584	3390 ± 540	NS
SGA (<10th percentile)	10 (6)	6 (4)	10 (15)	NS
LGA (>90th percentile)	6 (4)	24* (15)	12 (18)	<0.03
Prematurity (<37 wk) (% and No.)	6 (4)	6 (4)	8 (12)	NS
Hypoglycemia (<35 mg/dl) (% and No.)	2 (1)	13 (8)	5 (8)	<0.02
Hyperbilirubinemia (>12 mg/dl) (% and No.)	6 (4)	14 (9)	4 (6)	NS
Polycythemia (>65%) (% and No.)	2 (1)	14 (9)	3 (4)	<0.02
Neonatal intensive care admission (% and No.)	6 (4)	11 (7)	5 (7)	NS

*Group 2 versus group 1 and group 3.

women in the treated group (95% confidence interval, 1.04 to 80.9) for large-for-gestational-age infants.

Finally, the association between level of glycemia and neonatal size was evaluated. For groups 1 and 2, positive correlations were found between birth percentile and overall mean capillary blood glucose, preprandial and postprandial determinations ($r = 0.30$, $p < 0.01$; $r = 0.40, p < 0.005$; $r = 0.36, p < 0.004$, respectively).

Comment

The results of this randomized study provide insight into several key issues central to the continuing controversy surrounding the precise definition of gestational diabetes. For example, the glycemic profile of the treated and untreated patients with one abnormal oral GTT value were significantly different, suggesting that a single glycemic abnormality may herald a pattern similar to the well-established profile for an accepted case of gestational diabetes.[3, 7] The significant differences between neonatal outcome variables and the overall effect reflected in the significant relative risks for large infants in treated compared with untreated and control patients further underscores the importance of a single abnormal oral GTT result.

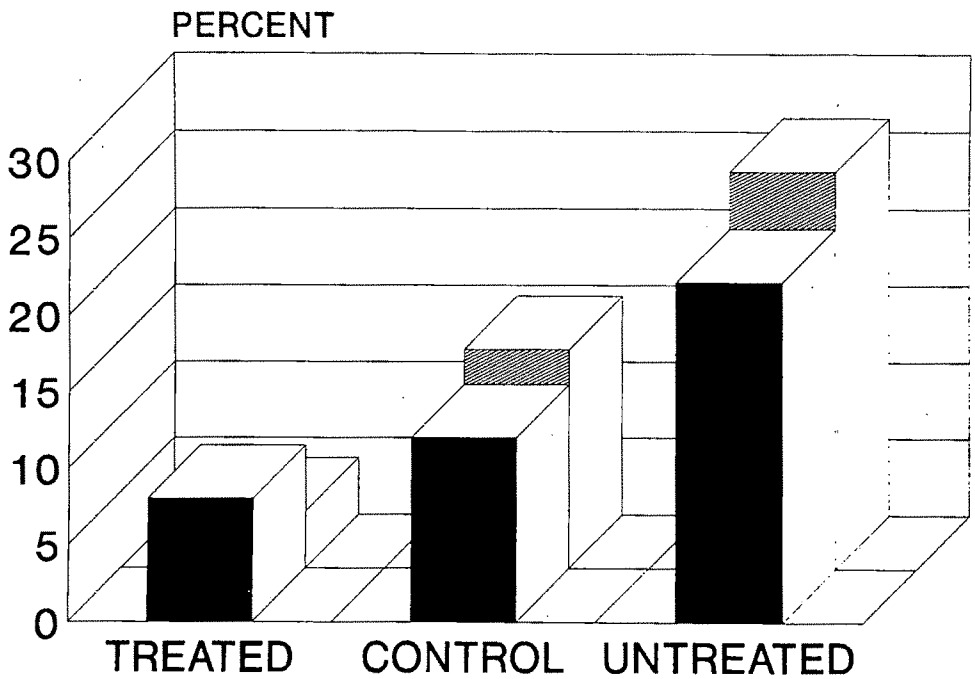

Fig. 3. Incidence of large infants in obese *(shaded area)* and nonobese *(darkened area)* women among three groups.

Previous studies of treated patients with gestational diabetes report a relatively high incidence of large infants. Furthermore, in a recent study comparing the World Health Organization and National Diabetes Data Group criteria, in which the latter served as the control (untreated), it was found that the incidence of large infants in the "control" was 28%.[10] In this investigation, although the overall mean birth weight was not significantly different between the groups, the incidence of large infants in the untreated group with one abnormal result parallels that expected from gestational diabetes. Thus it again suggests the congruence between the patients with one abnormal oral GTT with those patients with gestational diabetes mellitus who meet the National Diabetes Data Group criteria.

The inconsistent findings reported with regard to the association between level of glycemia and perinatal mortality and morbidity are the result of lack of uniformity in research methodology. The majority of studies were retrospective. The outcome was subject to the bias of clinical intervention (patient advised to modify her diet) in response to "borderline" oral GTT.

Few studies have concurrently included a nondiabetic control group. When a prospective design was used, randomization was not performed to measure the effect of intervention. There also was inconsistency in the definition of large infants. Some researchers used the 90th percentile standard growth curve, whereas others defined large infants as >4000 to 4500 gm.[11-16] These diverse factors have resulted in a wide variation in the reported prevalence of large infants.

The findings between the treated and untreated groups were significantly different. Therefore the high prevalence of unrecognized mild maternal hyperglycemia in the "normal" population (one abnormal result) may represent a group of patients with false-negative results or undiagnosed diabetes as suggested by the higher than expected incidence of large infants.

No association was discovered between the maternal variables evaluated and large infants. Although unexplained, the significantly older mean age of the treated group should have only contributed to more adverse outcome, which was not observed. Although advanced maternal age can be a factor contributing to macrosomia, it did not bias our result.

Contrary to the findings of other investigators[4, 12] who found an increased risk of preeclampsia, the incidence of hypertensive disorder was similar in the control and study groups. Thus it casts doubt on the relationship between level of glycemia and preeclampsia and women with a comparatively mild degree of hyperglycemia.

The data did not show any difference in maternal morbidity between the three study groups. Maternal weight gain was the single variable that showed a significant difference in the untreated group. This finding can be explained by the uncontrolled level of hyperglycemia.

There was a comparable rate of cesarean section

among the groups. Cesarean section as an outcome variable can reflect bias introduced by the liberal policy in many institutions with regard to method of delivery of the macrosomic infant. Future studies with a larger data base are needed to determine whether women with one abnormal oral GTT value are at greater risk for cesarean section.

The data we have presented strongly support the need to continue to refine the criteria for gestational diabetes. These findings conclusively demonstrate that neonatal morbidity can be substantially improved if treatment is provided the patient with just a single abnormal oral GTT value.

Routine umbilical cord blood gas determinations?

James A. Thorp, MD, Jone E. Sampson, MD, Valerie M. Parisi, MD, MPH, and Robert K. Creasy, MD

Houston, Texas

Between 1986 and 1988, 1924 term nulliparous patients with spontaneous onset of labor were studied to assess the importance of obtaining umbilical cord blood gas levels on all deliveries. The umbilical cord arterial and venous pH values (expressed as mean ± 2 SD) were 7.24 ± 0.14 (n = 1694) and 7.32 ± 0.12 (n = 1820), respectively. The incidence of newborn depression (1- or 5-minute Apgar score <7) was 14.1%; of these depressed newborns, the incidence of normal umbilical cord arterial pH values (≥ −2 SD) was 77.8%. Of the vigorous newborns, there was a 2.1% incidence of umbilical cord arterial blood acidemia. Umbilical cord arterial blood acidemia in vigorous newborns was not highly predictive of specific morbidity in the immediate newborn period. Regression analysis demonstrated the umbilical cord arterial pH to correlate best with the Apgar scores when compared with all other arterial or venous blood gas meaurements. We reached the following conclusions: (1) that obtaining cord arterial pH values in vigorous newborns should be considered since the values will provide objective documentation or normal fetal acid base balance in 98% of infants. (2) Only a cord *arterial* pH determination is recommended since it reflects fetal or newborn status more accurately than all other measurements. Additional measurements increase the likelihood of abnormal results and do not contribute to neonatal management. (3) An umbilical cord blood pH value is extremely useful in ruling out the diagnosis of birth asphyxia in the depressed newborn. (Am J Obstet Gynecol 1989;161:600-5.)

Key words: Umbilical cord blood pH, umbilical cord blood gas, vigorous newborn

Birth asphyxia is a relatively rare cause of major neurologic morbidity in children, despite the fact that it is the most commonly alleged cause in the courtroom. Recent studies estimate that less than 8% of cerebral palsy in children is actually related to birth asphyxia.[1, 2] Newborn depression is not a specific indicator of birth asphyxia. In fact, newborn depression has many diverse causes, including maternal drug ingestion, trauma, neonatal manipulation, congenital anomalies, prenatal fetal insults, prematurity, and finally, birth asphyxia, which is a relatively minor contributor. It is generally agreed that umbilical cord blood acidemia is the most sensitive indicator of birth asphyxia at the time of delivery. Most authorities agree that it is extremely important to obtain umbilical cord blood pH samples in the presence of newborn depression since it will rule out birth asphyxia in approximately 80% of cases.[3] However, the value of umbilical cord blood pH and gas measurement in the vigorous newborn is not clearly established. The purpose of this study was to assess the value of umbilical cord pH and gas measurements in the vigorous newborn.

Material and methods

Between 1986 and 1988, 1924 term nulliparous patients with spontaneous onset of labor, cephalic presentations, and singleton gestations were included in this study. We selected these patients to minimize the confounding variables of gestational age, abnormal presentations, multiple gestations, and parity. In addition, we chose to study only nulliparous patients since it is known that they have different mean cord blood pH values than multiparous patients.[4, 5] All of these patients' labors were managed according to the principles of active management of labor.[6] Labor was diagnosed by regular painful uterine contractions and cervical effacement, and was usually accompanied by either bloody show or rupture of membranes. Patients who were seen with fetal distress were not included in this study. After the diagnosis of labor was established, amniotomy was performed. If 2 cm of cervical dilatation did not occur within 2 hours of amniotomy, oxytocin augmentation was initiated. Oxytocin was administered by controlled intravenous infusion (model 960, IMED Corp., San Diego, Calif.) of 20 units of oxytocin diluted in 1 L of lactated Ringer's solution. Infusion was begun at 4 mU/min, increased by 4 mU/min every 15 minutes, and did not exceed a maximum dose of 36 mU/min. If uterine activity exceeded a frequency of seven contractions in 15 minutes, the oxytocin infusion rate was not increased, and possibly decreased. Continuous electronic fetal monitoring was performed in all patients.

Arterial and venous umbilical cord blood samples were obtained immediately after delivery and were placed on ice. Prepackaged, preheparinized 3 ml syringes (Marquest Medical products, Englewood, Colo.) were used to obtain a consistent preparation and concentration of heparin. Umbilical cord arterial and venous pH and gas measurements were performed routinely on all deliveries if possible. The blood gas analyzer (IL-1312, Instrumentation Laboratory, Lexington, Mass.) measured pH, P_{CO_2}, and P_{O_2} and calculated bicarbonate and base deficit. Cord blood gas analysis was routinely performed in a satellite laboratory, within 15 minutes of delivery under the supervision and direction of the Department of Pathology. In this study the 705 patients from 1986 and the 500 patients from 1988 had only umbilical cord pH values recorded in our investigational data base, whereas the 719 consecutive patients from 1987 also had the remainder of the gas measurements recorded. A "vigorous" newborn was defined as a newborn with normal Apgar scores (≥7 at 1 and 5 minutes). A depressed newborn was defined as a newborn with a 1- or 5-minute Apgar score of <7. Acidemic arterial and venous cord pH values were defined statistically as those being ≤2 SD below the mean for our population. Analysis of variance for the regression was performed with the Apgar score as the dependent variable, and each of the umbilical cord blood gas measurements, separately, as the independent variable. The 1-minute, 5-minute, and a combined 1- and 5-minute Apgar scores were used as the dependent variable in separate analyses. The umbilical arterial-venous difference of each of the gas measurements were also assessed as separate independent variables. Isolated respiratory acidemia in the umbilical cord arterial blood was defined by the following measurements: pH ≤ −2 SD, P_{CO_2} ≥ +2 SD, and a base deficit ≤ mean. Isolated metabolic acidemia in umbilical cord arterial blood was defined by the following measurements: pH ≤ −2 SD, base deficit ≥ +2 SD, and a P_{CO_2} ≤ mean. Although these definitions are arbitrary, they represent an accepted statistical standard for evaluation of a population with a normal Gaussian distribution. A microcomputer and appropriate software were used for assistance with the data base and statistical analyses (IBM PC XT, Symphony, Lotus Development Corp., Cambridge, Mass.; Abstat, Anderson-Bell, Parker, Colo.; SPSS, SPSS Inc., Chicago).

Results

Of the 1924 term nulliparous patients, 1919 had infants with 1- and 5-minute Apgar scores recorded on their medical charts. The 1-minute Apgar score was <7 in 268 newborns (14.0%), and the 5-minute Apgar score was <7 in 27 newborns (1.4%). The 1- or 5-minute Apgar score was <7 in 270 (14.1%), and the 1- and 5-minute Apgar score was <7 in 25 of 1919 newborns (1.3%). The umbilical cord arterial pH (mean ± SD) was 7.24 ± 0.07 (n = 1694), and the venous pH (mean ± SD) was 7.32 ± 0.06 (n = 1820). The remainder of the umbilical cord arterial and venous blood gas measurements are listed in Table I. In Table I, the n for the gas measurements other than the pH values is smaller since these values were only recorded on the 1987 portion of the investigational data base.

Table I. Umbilical cord blood gas measurements*

Umbilical cord artery	
pH	7.24 ± 0.07 (n = 1694)
P_{CO_2} (mm Hg)	56.3 ± 8.6 (n = 652)
P_{O_2} (mm Hg)	17.9 ± 6.9 (n = 651)
Bicarbonate (mEq/L)	24.1 ± 2.2 (n = 652)
Base deficit (mEq/L)	3.6 ± 2.7 (n = 652)
Umbilical cord vein	
pH	7.32 ± 0.06 (n = 1820)
P_{CO_2} (mm Hg)	43.8 ± 6.7 (n = 680)
P_{O_2} (mm Hg)	28.7 ± 7.3 (n = 680)
Bicarbonate (mEq/L)	22.6 ± 2.1 (n = 680)
Base deficit (mEq/L)	2.9 ± 2.4 (n = 680)

*All values listed as mean ± SD.

The frequencies of normal pH values with various combinations of abnormal Apgar scores are listed in Table II. The majority of depressed newborns (as previously defined) had normal umbilical cord blood pH values. Normal umbilical cord arterial pH values occurred in 77.8% (210 of 270) of depressed newborns as defined by a 1- or 5-minute Apgar score of <7. Table III demonstrates frequencies of umbilical cord and blood acidemia (variously defined) in vigorous newborns. There was a 2.1% incidence of cord arterial acidemia (≤7.10), 3.0% incidence of cord venous acidemia (≤7.20), and 4.0% incidence of cord arterial or venous acidemia. There was a twofold greater risk ($p < 0.005$) of finding umbilical cord blood acidemia in the vigorous newborn if both arterial and venous samples were considered (Table III).

Analysis of variance of the regression demonstrated cord arterial pH to correlate best (albeit poorly) with the Apgar scores, regardless of whether the 1-minute, the 5-minute, or a combination of both scores was used as the dependent variable. There was no combination of other arterial or venous pH/gas measurements, including the arterial-venous differences, that could approach the correlation of the umbilical cord arterial pH to the Apgar scores. Table IV demonstrates the correlation coefficient (r values), the F test for the analysis of variance for the regression, and the p values for each respective cord blood gas parameter in correlating with the 1-minute Apgar score. In Table IV, the umbilical cord gas measurements are listed in order of decreasing correlation with the 1-minute Apgar score. Similar re-

Table II. Frequency of normal umbilical cord pH values in newborns with abnormal Apgar scores*

	1 min Apgar score <7	*5 min Apgar score <7*	*1 or 5 min Apgar score <7*	*1 and 5 min Apgar score <7*
Normal umbilical cord arterial pH	208/244 (85.2%)	14/22 (63.6%)	210/270 (77.8%)	12/20 (60.0%)
Normal umbilical cord venous pH	221/256 (86.3%)	15/24 (62.5%)	223/258 (86.4%)	13/22 (59.1%)
Normal cord arterial pH and venous pH	198/240 (82.5%)	13/21 (61.9%)	200/242 (82.6%)	11/19 (57.9%)

*Normal umbilical cord pH values are defined as those values > −2 SD.

Table III. Frequency of umbilical cord blood acidemia in newborns with normal Apgar scores*

	No. affected/ total No.	%
Abnormal umbilical arterial pH (≤7.10)†	35/1690	2.1
Abnormal umbilical venous pH (≤7.20)	54/1816	3.0
Abnormal arterial or venous pH†	68/1682	4.0
Abnormal arterial and venous pH	21/1682	1.2

*Normal Apgar scores are defined as 1- and 5-minute scores of ≥7. Abnormal pH values are defined as a value that is ≤ 2 SD below the mean.

†There is a significant difference ($p < 0.005$) between these frequencies by χ^2 analysis.

lationships were observed with the 5-minute, or a combination of the 1- and 5-minute Apgar score when used as the dependent variable. Use of the combined 1- and 5-minute Apgar score yielded the best correlation coefficient (increase of 5%). The umbilical cord arterial pH, although correlating the best, still had a poor correlation (correlation coefficient = 0.31).

The majority of newborns with umbilical cord acidemia had a combination of metabolic and respiratory components. Isolated metabolic acidemia occurred in only 1 of 652 newborns. There were no cases of isolated respiratory acidemia among 652 newborns who had no missing arterial gas values. When the definition of isolated respiratory acidemia was broadened (pH ≤ −2 SD; P_{CO_2} ≥ 2 SD; base deficit ≤ +1 SD), it remained an unusual event (1 of 652).

Charts of all 35 of the 1690 vigorous newborns with umbilical cord arterial acidemia were reviewed. The mean umbilical cord arterial pH was 7.07 ± 0.03 (mean ± SD, $n = 35$). None of the 35 acidemic vigorous newborns or the 1655 nonacidemic vigorous newborns required admission to the neonatal intensive care unit. There was a significantly greater proportion ($p = 0.01$) of the acidemic vigorous newborns who required admission to the special care nursery (3 of 35, 8.6%), compared with the nonacidemic vigorous newborns (21 of 1655, 1.3%). One of the newborns was subsequently diagnosed as having a cardiac malformation (transposition), and the arterial cord blood bases values were as follows: pH, 7.10; P_{CO_2}, 68; P_{O_2}, 13; bicarbonate, 22; and base deficit, 9. Another infant had a neonatal seizure at 8 hours of life, and a cerebral hemorrhage, consistent with the diagnosis of birth asphyxia. The cord arterial blood gas values of this infant were as follows: pH, 7.08; P_{CO_2}, 74; P_{O_2}, 15; bicarbonate, 22; and base deficit, 9. The third infant had meconium aspiration syndrome; the cord arterial gas values were as follows: pH, 7.07; P_{CO_2}, 63; P_{O_2}, 13; bicarbonate, 19; and base deficit, 12. The duration of hospitalization for all 35 infants was 2.8 ± 1.9 (mean ± SD). There was no culture-documented infectious morbidity.

Comment

Umbilical cord blood pH is generally considered to be the most sensitive indicator of birth asphyxia.[3, 7, 8] As demonstrated in previous studies,[3, 7] the majority of depressed newborns (1- or 5-minute Apgar score <7) in our study also had normal cord blood pH values (Table II), thus ruling out the diagnosis of birth asphyxia, both in the delivery room and in the courtroom. The tremendous importance of obtaining cord blood pH measurement in the depressed newborn is generally recognized[3, 7-9]; however, the benefit of cord blood pH and gas values in the vigorous newborn is not well documented.

Our data are consistent with previous studies and demonstrate a small percentage of vigorous newborns with significant umbilical cord arterial acidemia. The cause of this acidemia in vigorous newborns is controversial. Some authors speculate that it may be of maternal origin.[10, 11] However, others provide convincing evidence that it may result from intrapartum asphyxia.[3, 8, 9] Previous studies suggest that neurologic impairment caused by birth asphyxia may develop in children with normal Apgar scores.[8] Brain damage by birth asphyxia in the monkey may be quite extensive in brainstem centers, and yet is hardly perceptible clinically.[12] The degree and duration of asphyxial insult necessary to produce brain damage probably varies, depending on several factors including fetal reserves, previous

Table IV. Correlation of umbilical cord gas measurements and the 1-minute Apgar score (listed in order of decreasing correlation)

Umbilical cord blood gas parameter	*n*	*Correlation coefficient*	*f ratio*	*p value**
Arterial pH	1690	0.31	189.0	<0.001
Venous pH	1816	0.29	169.5	<0.001
Arterial P_{CO_2}	652	0.27	51.3	<0.001
Venous P_{CO_2}	680	0.23	38.3	<0.001
Arterial P_{O_2}	651	0.18	22.6	<0.001
Arterial base deficit	652	0.18	22.1	<0.001

Venous P_{O_2}	680	0.10	7.3	<0.001
Arterial bicarbonate	652	0.04	0.9	NS
Venous bicarbonate	680	0.03	0.5	NS

**p* values and *f* ratios were obtained by analysis of variance of the regression with Apgar score at 1 minute used as the dependent variable and the umbilical cord gas parameter as the independent variable. The 5-minute Apgar score, or addition of the Apgar scores, yielded similar relationships; the addition of the Apgar scores improved the correlation coefficient by approximately 5%.

aphyxial insults, glucose loading or starvation, the metabolic status at the time of the insult, and the perfusion of the brain.[13] Studies in the fetal monkey have suggested that total anoxia in excess of 10 to 12 minutes will result in a neuropathologic state.[14] However, partial hypoxia with acidemia must be present for at least 2 hours before neuropathologic damage can be anticipated.[15] The finding that one of our acidemic vigorous newborns (Apgar scores of 7 and 9 at 1 and 5 minutes, respectively) had birth asphyxia is also consistent with these observations (i.e., birth asphyxia may occur in a newborn vigorous in the first minutes of life).

Umbilical cord blood acidemia in the vigorous newborn was not highly predictive of a specific morbidity in the early newborn period. Contrary to popular opinion, cord blood acidemia in the vigorous newborn did not predict newborn sepsis in our study. However, three of 35 acidemic vigorous newborns had significant morbidity in the early newborn period. Although acidemia was poorly predictive of nonspecific morbidity and provided supporting evidence for the diagnosis of birth asphyxia in one vigorous newborn, the clinical benefit derived from umbilical cord blood acidemia in the vigorous newborn was limited. It may be speculated that of the three acidemic vigorous newborns described, the acidemic cord arterial pH could be harmful to the obstetrician in court in the cases of the infant with meconium aspiration and the infant with early neonatal seizures, but probably not in the infant with the cardiac anomaly. Similarly, one could speculate that all the acidemic vigorous newborns (2%) could potentially be labeled as asphyxiated in court. It is important to consider that the majority of children with neurologic deficits are vigorous at birth, and that cord blood acidemia is a poor predictor of neurologic deficit at 1 year of life.[16] Unfortunately, a plaintiff's attorney may allege birth asphyxia as the cause of neurologic deficit regardless of whether there is an absent cord pH or an acidemic cord pH on the medical record. The vulnerability of the obstetrician would depend not only on the acidemic cord arterial pH, since that information was obtained after delivery, but also on the intrapartum management that was based on the fetal heart rate tracing. It should be emphasized, however, that obtaining umbilical cord arterial pH values in the vigorous newborn will provide objective documentation that rules out the diagnosis of birth asphyxia in approximately 98% of vigorous newborns.

Experts in litigation involving potential birth asphyxia suggest that the Apgar score is a very subjective evaluation, and may be biased by delivery room staff; these opinions are also shared by many physicians.[3, 7, 8] Indeed, the only Apgar parameter with an objective end point is the pulse; the others (respiratory effort, muscle tone, reflex irritability, and color) are subjective. The Apgar scores are assigned by delivery room staff, who may give high scores because of fear of criticism from colleagues. In addition, the Apgar scores are often assigned retrospectively. In contrast, the cord arterial pH is determined by staff outside the department by means of a machine that is required to be maintained and reviewed by rigorous quality assurance policies. For these reasons, an objective measurement of umbilical cord pH in the vigorous newborn may be a judicious medicolegal practice if performance is impaired in postnatal life.

Previous data in the literature suggest that cord arterial pH is the most accurate reflection of fetal and newborn status when compared with all other cord arterial and venous blood gas measurements.[3, 7, 8, 11, 17] This observation is based primarily on correlation of blood gas measurements with Apgar scores, in addition to anatomic relationships of fetal circulation. Umbilical arterial blood, in general, reflects fetal tissue status, and umbilical venous blood reflects placental function and fetal status. Our study is consistent with the previous

literature. There was no combination of, or arterial-venous differences between, the pH, P_{CO_2}, P_{O_2}, bicarbonate, or base deficit values, which correlated with the Apgar scores, as well as the cord arterial pH. Also consistent with the observations of others[8, 11] is the very poor correlation between the cord blood P_{O_2} and the fetal status or the Apgar scores.

Some authorities[18] suggest that the P_{CO_2} and base deficit may be important in differentiation of respiratory acidemia and metabolic acidemia. Adult respiratory physiology would support the concept that respiratory acidemia caused by carbon dioxide retention will precede a metabolic acidemia caused by hypoxia. Unfortunately, our data and that of others[8] suggest that an isolated respiratory acidemia in umbilical cord blood is extremely rare, and that acidemia is almost exclusively of mixed respiratory and metabolic origins. We arbitrarily chose to define isolated respiratory acidemia ($pH \leq -2$ SD; $P_{CO_2} \geq +2$ SD; base deficit $\leq$ mean) and isolated metabolic acidemia ($pH \leq -2$ SD; $P_{CO_2} \leq$ mean; base deficit $\geq +2$ SD) statistically. Even when these definitions were broadened, similar findings were noted (i.e., the majority of cord blood acidemia was mixed, and isolated respiratory acidemia was an absent, or unusual finding). Thus it is unlikely that obtaining the other gas parameters will demonstrate an isolated respiratory acidemia. Therefore, although of academic interest, the value of obtaining measurements other than the umbilical cord arterial pH may be limited.

We believe that although our statistical definitions of cord blood gas parameters are accurate, they should be evaluated for clinical usefulness in large populations. Definitions of abnormal fetal cord blood gas parameters derived clinically rather than statistically may vary widely among institutions. These differences in definition subsequently do not allow for standardized comparisons of cord gas values among various populations, whereas values expressed in SD above or below the mean are universally applicable. In addition, we believe that the review of both umbilical arterial and venous cord blood gases may be clinically useful in certain patients by providing insight into the evaluation of intrapartum events and the resultant response to neonatal resuscitation.

If an institution chooses to obtain cord pH values in all deliveries, the best single parameter is cord arterial pH. It is the most accurate reflection of fetal and newborn status. Obtaining additional measurements, such as a cord venous pH, in the vigorous newborn results in a twofold greater chance ($p < 0.005$) of finding an acidemic result (Table III). This rise in frequency of acidemia in the vigorous newborn would increase anxiety without providing any additional clinically useful information for neonatal management.

The Apgar score has only a limited correlation with long-term neurologic outcome. An infant with an Apgar score of 0 to 3 at 5 minutes and ≥ 4 at 10 minutes has a 99% chance of not having cerebral palsy at 7 years of age.[19] One study found a 12.7% incidence of abnormal neurologic findings at 1 year of age if the 5-minute Apgar score was <7, and 1.7% incidence if the Apgar scores were normal.[20] There is a paucity of data with regard to the long-term outcome of newborns with cord blood acidemia. Initial studies[9, 16] suggest that the majority of newborns with cord blood acidemia have normal neurologic development. One study of term infants with metabolic acidemia at birth demonstrated no increased risk of neurologic or developmental problems when compared with newborns who had normal acid-base values.[9] Another study found that cord blood acidemia in newborns had a poor positive predictive value (only 8%) when used to assess adverse outcome at 1 year of life.[16] These observations are further supported by a recent study demonstrating that only 8% of cerebral palsy in children was possibly related to intrapartum asphyxia.[1, 2] The majority of neurologic lesions may occur before labor or be unrelated to birth asphyxia. Therefore a poor correlation between neurologic impairment and low Apgar scores or cord acidemia should be expected. Ultrasonography has clearly demonstrated significant neurologic lesions in the fetus well before the onset of labor. When neurologic deficit occurs, lay jurors are easily persuaded to believe that minor deviations from the standard of care at birth caused the deficit and often support excessive and unwarranted awards. Objective cord blood pH measurements reduce this possibility.

Cost consideration is certainly a relevant factor. Expenditure reductions of approximately 86% will occur if an institution chooses to selectively obtain cord blood studies only when deliveries result in depressed newborns (i.e., only approximately 14% of newborns will be depressed). Unfortunately, selective use will inevitably result in failure to obtain umbilical cord blood pH measurement in at least some depressed newborns as a result of the anxiety and confusion of emergency situations and the lack of an established routine. In our institution umbilical cord arterial and venous pH and gas measurement have been obtained on all deliveries since 1986. We have chosen to charge for this by adding a cost of $20 to all deliveries and therefore we do not bill separately for this service. This cost might be significantly reduced if a pH analyzer rather than a blood gas analyzer were used.

We derived the following conclusions from this study. (1) Obtaining umbilical cord arterial pH values in the vigorous newborn should be considered since it will provide objective documentation of normal fetal and newborn acid-base balance and by inference, metabolic status, in 98% of infants. (2) Only a cord *arterial* pH

determination is recommended since it reflects fetal and newborn status more accurately than all other measurements, and additional measurements increase the likelihood of abnormal results, without contributing to neonatal management. (3) As others have shown, an umbilical cord blood pH is also useful in ruling out the diagnosis of birth asphyxia in the depressed newborn.

Comparison of six different ultrasonographic methods for predicting lethal fetal pulmonary hypoplasia

Anthony M. Vintzileos, MD, Winston A. Campbell, MD, John F. Rodis, MD, David J. Nochimson, MD, Michael G. Pinette, MD, and Boris M. Petrikovsky, MD
Farmington, Connecticut

Nomograms of six different ultrasonographic fetal parameters were established by studying uncomplicated, singleton pregnancies, with well-established dates, between 16 and 40 weeks of gestation. The studied parameters could reflect fetal lung mass and included the following: chest circumference (CC), chest area (CA), chest area minus heart area (CA − HA), chest circumference/abdominal circumference ratio (CC × 100/AC), chest area/heart area ratio (CA/HA), and chest area minus heart area divided by chest area ratio [(CA − HA) × 100/CA]. The effect of ruptured membranes on these six ultrasonographic parameters was assessed by studying patients who had premature rupture of the membranes of <1 week's duration. It was found that premature rupture of the membranes is associated with increased frequency of CC, CA, and CA − HA measurements at or below the 5th percentile. However, in patients with premature rupture of the membranes all measurements were within the normal range for the three ratios. The efficacy of each of the six parameters was determined by studying 13 fetuses at high risk for development of lethal pulmonary hypoplasia. The (CA − HA) × 100/CA parameter had the best diagnostic accuracy (sensitivity 85%, specificity 85%, positive predictive value 83%, and negative predictive value 85%). (Am J Obstet Gynecol 1989;161:606-12.)

Key words: Ultrasonography, fetal pulmonary hypoplasia

Fetal pulmonary hypoplasia is commonly associated with both renal and nonrenal origins of decreased amniotic fluid.[1-4] There is a wide spectrum of clinical manifestations of pulmonary hypoplasia that ranges from acute respiratory failure leading to early neonatal death (lethal form) to respiratory insufficiency including pulmonary hemorrhage, severe bronchopulmonary dysplasia, subacute lung disease, or transient respiratory disease (nonlethal form).[5] From the clinician's standpoint the antepartum prediction of lethal pulmonary hypoplasia would be very beneficial with regard to both obstetric management and parental counseling.

In the past, two main ultrasonographic techniques have been used to diagnose pulmonary hypoplasia: chest circumference measurements and chest circumference/abdominal circumference (CC/AC) ratio.[6-10] Nomograms for chest circumferences throughout gestation have been developed by previous investigators.[6-8] The use of chest circumference nomograms, however, requires accurate knowledge of the length of gestation. Therefore these nomograms cannot be used in fetuses with unknown gestational age or fetuses with suspected intrauterine growth retardation, which is frequently present. To circumvent these drawbacks some investigators have proposed the use of a gestational age–independent ratio (CC/AC)[9,10] or nomograms that allow for comparison of the chest circumference with other ultrasonographic parameters (e.g., biparietal diameter, head circumference, abdominal circumference, femur length), which hopefully are not affected when growth or structural abnormalities are present.[11] These quantitative interthoracic relationships, however, may be misleading in cases where growth or structural abnormalities do not compromise the various fetal parameters to the same degree. An additional limitation of the previously established chest circumference nomograms is that measurements were derived from outer edge to outer edge of the fetal thorax, and therefore their use in fetuses with excessive subcutaneous tissue and skin may give erroneous results. For instance, normal chest circumference measurements have been described in a fetus with wrinkled skin (Pena-Shokeir syndrome) and lethal pulmonary hypoplasia.[8]

The major advantage of the CC/AC ratio is that it is gestational age independent and could be reliably used without accurate knowledge of the gestational age. The major limitation is that it cannot be used in fetuses with large chest circumferences caused by excessive skin and subcutaneous tissue or in conditions that affect or distort abdominal circumference measurements (e.g., fetuses with polycystic kidneys, obstructive uropathy, om-

phalocele). It is known that many cases of pulmonary hypoplasia are due to prolonged premature rupture of the membranes (PROM); in these cases, however, the use of the two commonly used parameters (chest circumference measurements and AC/CC ratio) is questionable since the effect of PROM on these measurements has not been investigated.

The antenatal diagnosis of pulmonary hypoplasia is always suspected by the subjective impression of cardiothoracic disproportion noted during an ultrasonographic examination. Since it is important to quantitatively assess the intrathoracic structures when abnormal lung development is suspected, the present study was undertaken with the following objectives: (1) to establish nomograms of six different ultrasonographic parameters that could reflect fetal lung mass, (2) to assess the effect of PROM on these parameters, and (3) to determine the usefulness of these parameters in predicting lethal pulmonary hypoplasia in high-risk fetuses.

Material and methods

In the present study the first step was to establish the nomograms of the six fetal parameters throughout gestations. One hundred eighty-one uncomplicated pregnancies between 16 and 40 weeks of gestation (dates confirmed by early ultrasonography) were used for single ultrasonographic measurement to generate the nomograms in a cross-sectional manner. All patients had intact membranes and singleton pregnancies. Delivery occurred within 2 weeks of the predicted date of delivery either by spontaneous labor or by elective repeat cesarean section. Patients with an abnormal fetal outcome (e.g., congenital anomalies, intrauterine growth retardation, fetal macrosomia) were excluded. The ultrasonographic examinations were performed with a linear-array real-time ultrasonographic instrument (GE 3000 or Acuson 128) with a 3.5 or 5.0 MHz transducer. Freeze-frame capabilities were available, and on-screen calipers were used for the measurements. The ultrasound velocity was 1540 m/sec. In addition to routine biometry, the bony chest circumference (CC), chest area (CA), heart circumference (HtC), and heart area (HA) were determined from a cross section of the fetal chest at right angles to the fetal spine at the level of the atrioventricular valves with the heart in ventricular diastole (Fig. 1). From this view, the circumferences were directly measured and the areas were automatically calculated. For the purpose of this study the relationship between gestational age and each of the following six parameters was defined: CC, CA, (CA − HA), CC × 100/AC, CA/HA, and (CA − HA) × 100/CA. Scattergrams with increasing gestational age were developed and regression analyses were used to establish the nomograms including the 5th, 50th, and 95th percentile lines. The statistical analysis of the data was performed by computer (Macintosh II) with the StatView 512+ and Cricket Graph statistical packages.

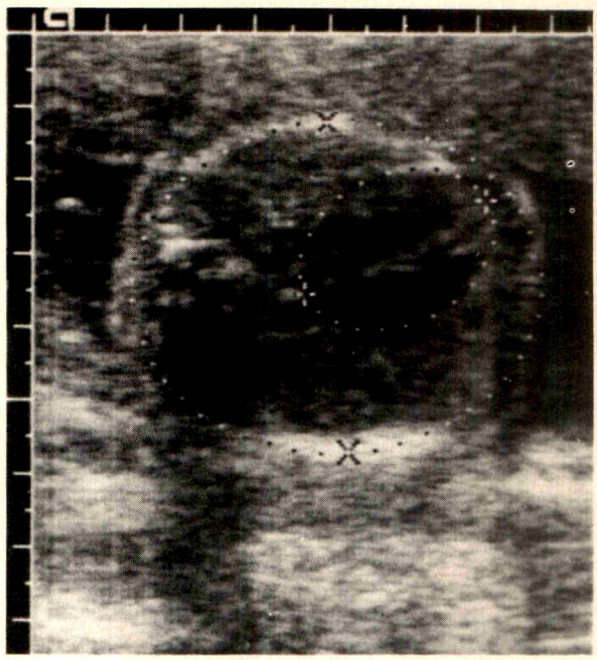

Fig. 1. Ultrasonographic photograph showing cross section of fetal chest at level of four-chamber view, illustrating placement of calipers for measurements of bony chest circumference and heart circumference. Areas are automatically calculated.

After the nomograms were established, the second step was to assess the effect of PROM by studying 18 patients with ruptured membranes not at risk for pulmonary hypoplasia (duration of PROM <1 week). All 18 patients had a single measurement within 1 week of delivery and none of the infants developed any signs of pulmonary hypoplasia. The measurements of the groups with intact versus ruptured membranes were compared by Fisher's exact and two-tailed t tests. A value of $p < 0.05$ was considered to be statistically significant.

The efficacy of each of the six parameters to predict lethal pulmonary hypoplasia (third step) was determined by studying 13 fetuses at high risk. Four of these fetuses had renal anomalies (three obstructive uropathy and one bilateral polycystic kidney disease), four had PROM at <26 weeks' gestation and >5 weeks' duration, and five had idiopathic oligohydramnios. All 13 fetuses had severe oligohydramnios, as defined by largest vertical amniotic fluid pocket <1 cm, of at least 5 weeks' duration. The last examination within 1 week of delivery was used for analysis. Of the 13 high-risk fetuses, six developed lethal pulmonary hypoplasia, three developed respiratory insufficiency compatible with clinical pulmonary hypoplasia but survived, and the re-

maining four did not show any signs of pulmonary hypoplasia. Since the prediction of lethal pulmonary hypoplasia may alter obstetric management, the efficacy (sensitivity, specificity, and positive and negative predictive values) of each of the six parameters to predict lethal pulmonary hypoplasia only was addressed. Measurements at or below the 5th percentile were considered abnormal. All six neonates with lethal pulmonary hypoplasia died in the first 48 hours after birth, and the diagnosis was confirmed at autopsy by lung weight/body weight ratios and radial alveolar counts.[12]

Results

The best-fit curves were second- and third-degree polynomials for chest circumference and chest area, respectively. The regression equation for chest circumference versus gestational age was: $y = -10.315 + 1.35x - 0.009x^2$($R^2 = 0.902$) and for chest area versus gestational age was: $y = 36.36 - 5.176x + 0.253x^2 - 0.003x^3$ ($R^2 = 0.848$). The relationship between CA − HA and gestational age was linear ($y = -24.954 + 1.7142x$, $R^2 = 0.740$). Regression analyses of the relationships among the three ratios [CC × 100/AC, CA/HA, and (CA − HA) × 100/CA] and gestational age revealed these ratios to be relatively constant. The mean value for CC/AC × 100 was 85 (5th to 95th percentile range, 75 to 95). The regression of this ratio versus gestational age revealed that this ratio decreases only at a rate of 0.125 units per week ($R = 0.091$, $R^2 = 0.008$, SE = 0.055, $F = 1.492$, intercept = 0.877, and slope = −0.001). The regression of CA/HA versus gestational age revealed that this ratio decreases only at a rate of 0.031 units per week of gestation ($R = 0.179$, $R^2 = 0.032$, SE = 0.836, $F = 5.951$, intercept = 4.629, and slope = −0.027). The regression of (CA − HA) × 100/CA revealed that this ratio decreases only at a rate of 0.312 units per week ($R = 0.22$, $R^2 = 0.049$, SE = 0.068, $F = 9.13$ intercept = 0.814, and slope = −0.003). Regression analyses were also used to define the relationships between CC versus AC, CA versus HA, and (CA − HA) versus CA. All three plots were linear with high R^2 values (0.920, 0.86, and 0.957), which further substantiates the hypothesis that all three ratios are relatively constant between 16 and 40 weeks of gestation. The intraobserver and interobserver variabilities were ≤8% for all parameters, the lowest being 2.6% for CC (intraobserver) and the highest 8% for HA (interobserver).

After having established the nomograms, the effect of PROM was assessed by studying 18 patients with PROM (gestational ages between 22 and 36 weeks). The measurements of these patients were compared to the nomograms (including the mean and the 5th and 95th percentile lines) as established from the patients with intact membranes. Chest circumference measurements were at or below the 5th percentile in 6 of 18 patients (33.3%) with PROM versus 15 of 181 (8.2%) with intact membranes ($p < 0.05$); 4 of 18 (22.2%) with PROM versus 9 of 181 (4.9%) with intact membranes had CA measurements at or below the 5th percentile ($p < 0.05$); and 4 of 18 (22.2%) with PROM versus 6 of 181 (3.3%) with intact membranes had CA − HA measurements at or below the 5th percentile ($p < 0.05$). The frequency of measurements at or below the 5th percentile for patients with PROM was the highest for gestational ages <28 weeks. Table I compares the three ratios (5th, mean, and 95th percentiles) between patients with intact and ruptured membranes. Although patients with PROM had lower mean values for CA/HA and (CA − HA) × 100/CA (3.74 versus 3.10 and 74 versus 68, respectively; $p < 0.05$), there were no differences in the 5th percentiles for any of the three ratios between patients with intact and ruptured membranes, and all patients with PROM had measurements within the normal range (between the 5th and 95th percentile).

As a third step in the study, the efficacy of the six ultrasonographic parameters to predict lethal pulmonary hypoplasia in 13 fetuses at high risk was determined. A total of six fetuses developed lethal pulmonary hypoplasia. There were five fetuses with CC measurements at or below the 5th percentile for gestational age, only two of whom developed lethal pulmonary hypoplasia. From four fetuses with CA measurements at or below the 5th percentile only two developed lethal

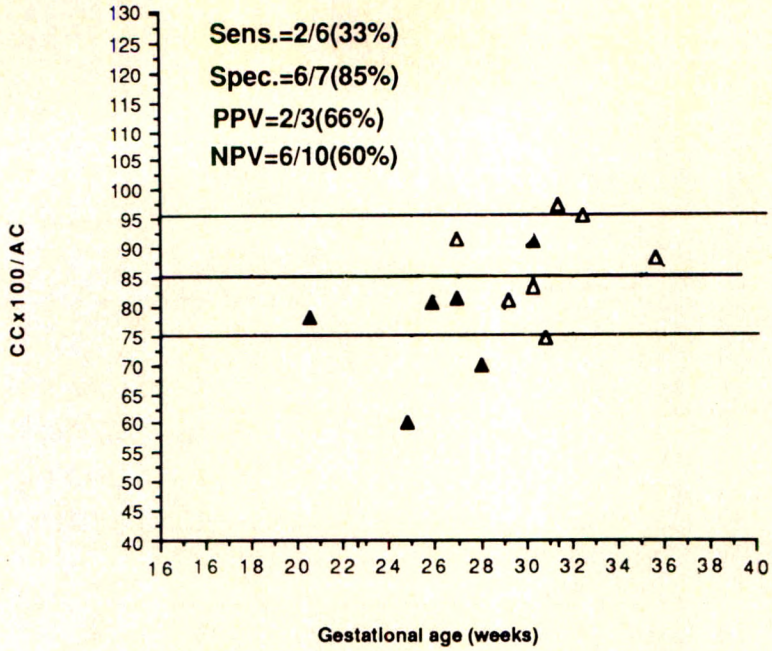

Fig. 2. Graph illustrating distribution of CC/AC ratios of 13 fetuses at risk for pulmonary hypoplasia (*solid triangles*, lethal pulmonary hypoplasia; *open triangles*, no lethal pulmonary hypoplasia). Values at or below 5th percentile were considered abnormal.

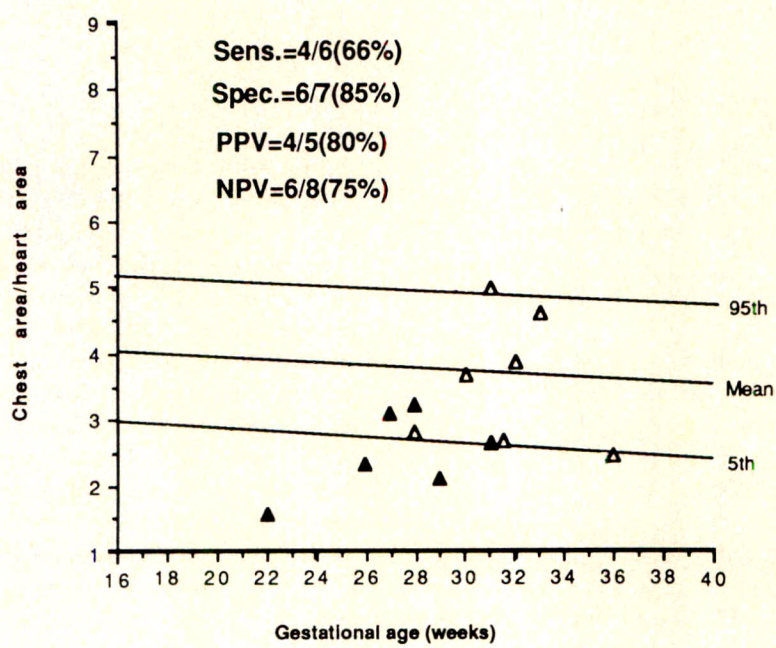

Fig. 3. Graph illustrating distribution of chest area/heart area ratios of 13 fetuses at risk for pulmonary hypoplasia (*solid triangles*, lethal pulmonary hypoplasia; *open triangle*, no lethal pulmonary hypoplasia). Values at or below 5th percentile were considered abnormal.

pulmonary hypoplasia, and from five fetuses with CA − HA measurements at or below the 5th percentile only three developed lethal pulmonary hypoplasia. Figs. 2, 3, and 4 illustrate the distribution of the three ratios of the 13 fetuses at risk. The (CA − HA) × 100/CA ratio had the best diagnostic accuracy (sensitivity 85%, specificity 85%, positive predictive value 83%, negative predictive value 85%, and overall efficiency 85%). Table II summarizes the efficacy of the six fetal parameters to predict lethal pulmonary

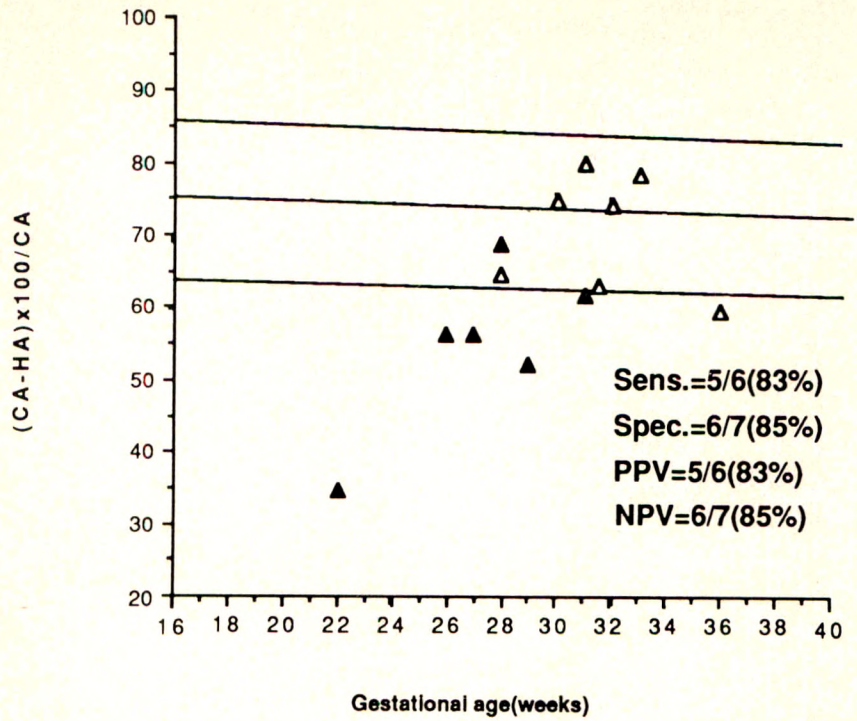

Fig. 4. Graph illustrating distribution of (CA − HA) × 100/CA ratios of 13 fetuses at risk for pulmonary hypoplasia (*solid triangles*, lethal pulmonary hypoplasia; *open triangles*, no lethal pulmonary hypoplasia). Values at or below 5th percentile were considered abnormal.

hypoplasia. Other parameters, such as CC − HtC, CC/HtC, and (CC − HtC)/CC, as well as interthoracic relationship nomograms (e.g., femur length vs. CC, CA, and CA − HA), were also established, but these did not improve diagnostic accuracy in predicting lethal pulmonary hypoplasia.

Comment

The presence of pulmonary hypoplasia has been well documented in fetuses with long-standing oligohydramnios, which could be the result of chronic amniotic fluid leakage or fetal renal disease or it could be idiopathic. The extent of fetal pulmonary hypoplasia depends on the degree of oligohydramnios, its duration, and the gestational age and stage of lung development when it occurs.[4] A spectrum of pulmonary hypoplasia can therefore be expected, ranging from mild transient respiratory disease to severe respiratory insufficiency leading to death in the immediate neonatal period.[5] From the clinician's standpoint it would be desirable to consider hypoplasia as either lethal or nonlethal. Although prediction of the nonlethal forms of pulmonary hypoplasia may or may not change obstetric management, prediction of the lethal form during the antepartum period may drastically alter obstetric management. It was for this reason, as well as the controversies surrounding the clinical diagnosis of pulmonary hypoplasia in surviving infants, that the present study was undertaken with the prediction of the lethal form of pulmonary hypoplasia used as an endpoint.

Previous investigators have attempted to make the antenatal diagnosis of lethal and nonlethal forms of pulmonary hypoplasia by using nomograms of chest circumference measurements throughout gestation,[6-8] interthoracic relationship nomograms (chest circumference measurements versus biparietal diameter, head circumference, abdominal circumference, or femur length),[11] or the CC/AC ratio, which has the advantage of being constant throughout gestation.[9, 10] Since the clinical setting of pulmonary hypoplasia is frequently accompanied by structural and growth abnormalities, the use of interthoracic nomograms is appropriate but only in cases where the different fetal organs are compromised to the same degree as the chest circumference. In many cases, however, the various fetal parameters are not equally compromised. Therefore, the idea of quantitatively defining intrathoracic growth relationships (e.g., heart or bony chest measurements) is attractive, and it was pursued in this study without including the skin and subcutaneous tissue in the thoracic measurements. In fetuses with obstructive uropathy or polycystic kidney disease who are at substantial risk for pulmonary hypoplasia, the use of the CC/AC ratio is inappropriate because of the frequently observed abdominal enlargement, which is secondary to the distended urinary tract. The use of this ratio is also in-

Table II. Efficacy to predict lethal pulmonary hypoplasia

Ultrasonographic parameter	*Sensitivity (%)*	*Specificity (%)*	*Positive predictive value (%)*	*Negative predictive value (%)*	*Test efficiency (overall) (%)*
CC	33	57	40	50	46
CA	33	71	50	55	54
CA-HA	50	71	60	62	62
CC × 100/AC	33	85	66	60	62
CA/HA	66	85	80	75	77
(CA-HA) × 100/CA	85	85	83	85	85

CC, Chest circumference; *CA*, chest area; *HA*, heart area; *AC*, abdominal circumference.

appropriate in the presence of fetal congenital anomalies such as omphalocele, ascites, diaphragmatic hernia, etc., which may distort or alter the abdominal circumference measurements. With the above considerations in mind the present cross-sectional study was undertaken with one of the major objectives to be the establishment of nomograms of ultrasonographic parameters that possibly could reflect fetal lung mass by studying 181 uncomplicated pregnancies with intact membranes at the time of the examination. Two of the six studied parameters were chest circumference measurements and CC/AC ratio. The relationship between gestational age and bony chest circumference measurements was curvilinear and the best fit was a second-degree polynomial equation. In some previous studies[6, 7] the relationship between gestational age and chest circumference measurements has been found to be linear. The mean, 5th, and 95th percentile values established in the present study were somewhat less than the corresponding values of the previously published nomograms.[6, 8] These differences can be explained by the different method that we used; specifically, we measured the bony chest circumference instead of measuring from outer edge to outer edge of the fetal thorax as done previously. For the same reason the CC/AC ratio was found to be somewhat less than previously reported norms (mean values 0.91 to 0.94 in previous studies[8, 10] versus 0.85 at the present study). In the present study the relationship between gestational age and chest area was found to be curvilinear with the best fit being a third-degree polynominal equation, whereas the relationship between gestational age and CH − HA was linear. One of the interesting findings of the present study was that the remaining two intrathoracic ratios (CA/HA) and [(CA − HA) × 100/CA] remained relatively constant throughout gestation and therefore could be used in patients with unknown or uncertain dates.

Although previous investigators have reported on the ability of chest circumference measurements and CC/AC ratio to predict pulmonary hypoplasia, there are significant differences between those studies and the present study in regards to methods, design, and prediction of nonlethal versus lethal forms of pulmonary hypoplasia. In the majority of previous studies fetuses at risk for pulmonary hypoplasia because of prolonged rupture of the membranes were evaluated by use of nomograms established from patients with intact membranes. However, rupture of the membranes by itself is known to cause fetal compression and therefore may be inherently associated with alterations in fetal biometry. The present study addressed the latter point by evaluating fetuses with ruptured membranes who were very unlikely to develop pulmonary hypoplasia since the duration of PROM was <1 week. It was found that PROM itself is associated with decreased thoracic measurements. Fetuses with PROM had a significantly higher frequency of measurements at or below the 5th percentile for CC (33.3%), CA (22.2%) and CA − HA (22.2%). This effect of PROM on these measurements was most pronounced at <28 weeks' gestation. The finding of the same mean value, as well as range, for CC/AC ratio would suggest that the same degree of thoracic and abdominal compression exists in the presence of PROM. In all cases with PROM, however, the measurements were within the normal range for all three gestational age–independent ratios. The fact that the 5th percentiles of the three ratios are not altered by the presence of PROM makes them potentially valuable tools for evaluating fetuses with prolonged PROM and fetuses of uncertain gestational ages.

As noted in Table II, most parameters had low positive and negative predictive values to be clinically useful. Other parameters, such as CC − HtC, CC/HtC, and (CC − HtC)/CC, were also studied as were interthoracic relationship nomograms (femur length vs. CC, CA, and CA − HA). However, these did not improve diagnostic accuracy. Most parameters had disappointingly low sensitivities. The diagnostic accuracies of the studied parameters were much lower than those of previous reports.[7, 10] This discrepancy may be due to: (1) differences in the populations studied; (2) inclusion of fetuses at particularly high risk for development of pulmonary hypoplasia in this study (all had documented oligohydramnios of >5 weeks' duration); and (3) dif-

ferences regarding the end point of prediction, which in our study was the lethal form of the disease. In the present study the (CA − HA) × 100/CA ratio had the best diagnostic accuracy (85%). This ratio is gestational age independent and it is not altered by PROM; in addition it can be used in fetuses with large or distorted AC (e.g., obstructive uropathy, omphalocele, etc.) where the use of CC/AC is inappropriate. We are continuing to evaluate the use of this ratio in our institution by collecting data from a larger number of fetuses.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1989 issues from the Publisher, at a cost of $56.00 ($79.00 international) for Vol. 160 (January-June) and Vol. 161 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C.V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146-3318, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Presenting the Only Desk Calendar Designed Exclusively for the Busy Physician and Surgeon!

THE PHYSICIANS AND SURGEONS ILLUSTRATED DESK DIARY 1989-1990

Keeping your special needs and demands in mind, we've designed this exquisite 15-month desk calendar especially for you. A delight to give or receive--you'll want to share it with your friends and colleagues. At your request, we'll mail a personal desk calendar directly to them with a card from you. But order now--the supply is limited.

- *66 captivating reproductions of works by such well-known artists as Michelangelo, Rockwell, Hannah, and Metsu*
- *dates and locations of the major medical and surgical meetings in 1990*
- *all you need to plan your convention schedule --major airports and airlines, hotels and restaurants, including locations and telephone numbers*
- *high quality paper with gilt edges, classic ribbon marker and luxurious leather-bound cover (elegant cloth-bound cover also available)*

Act fast--
there will be only one printing, so supply is limited!
September, 1989. Approx. 160 pages, 66 illustrations including 50 in full color! Leather (Book Code: **06206**); Cloth (Book Code: **06205**)

To order, call toll-free: 800-221-7700, ext. 15A

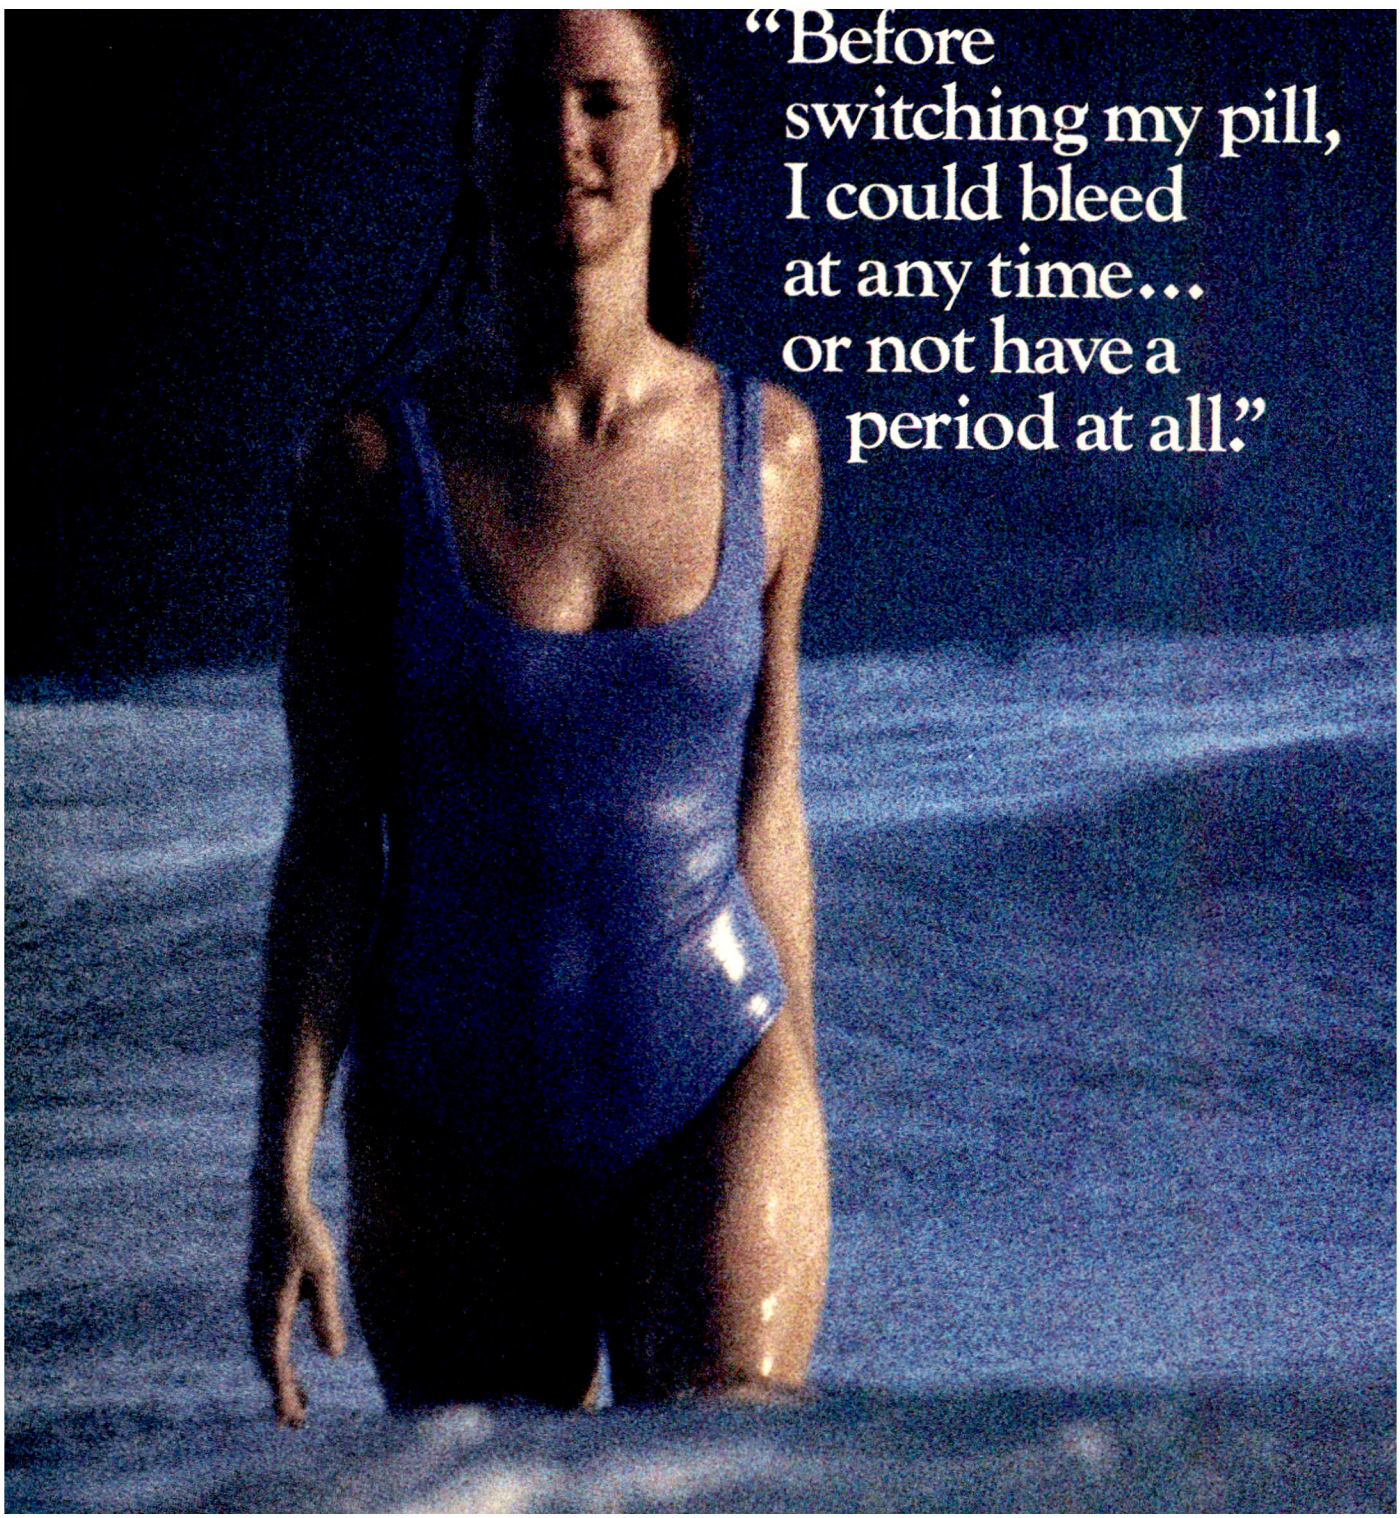
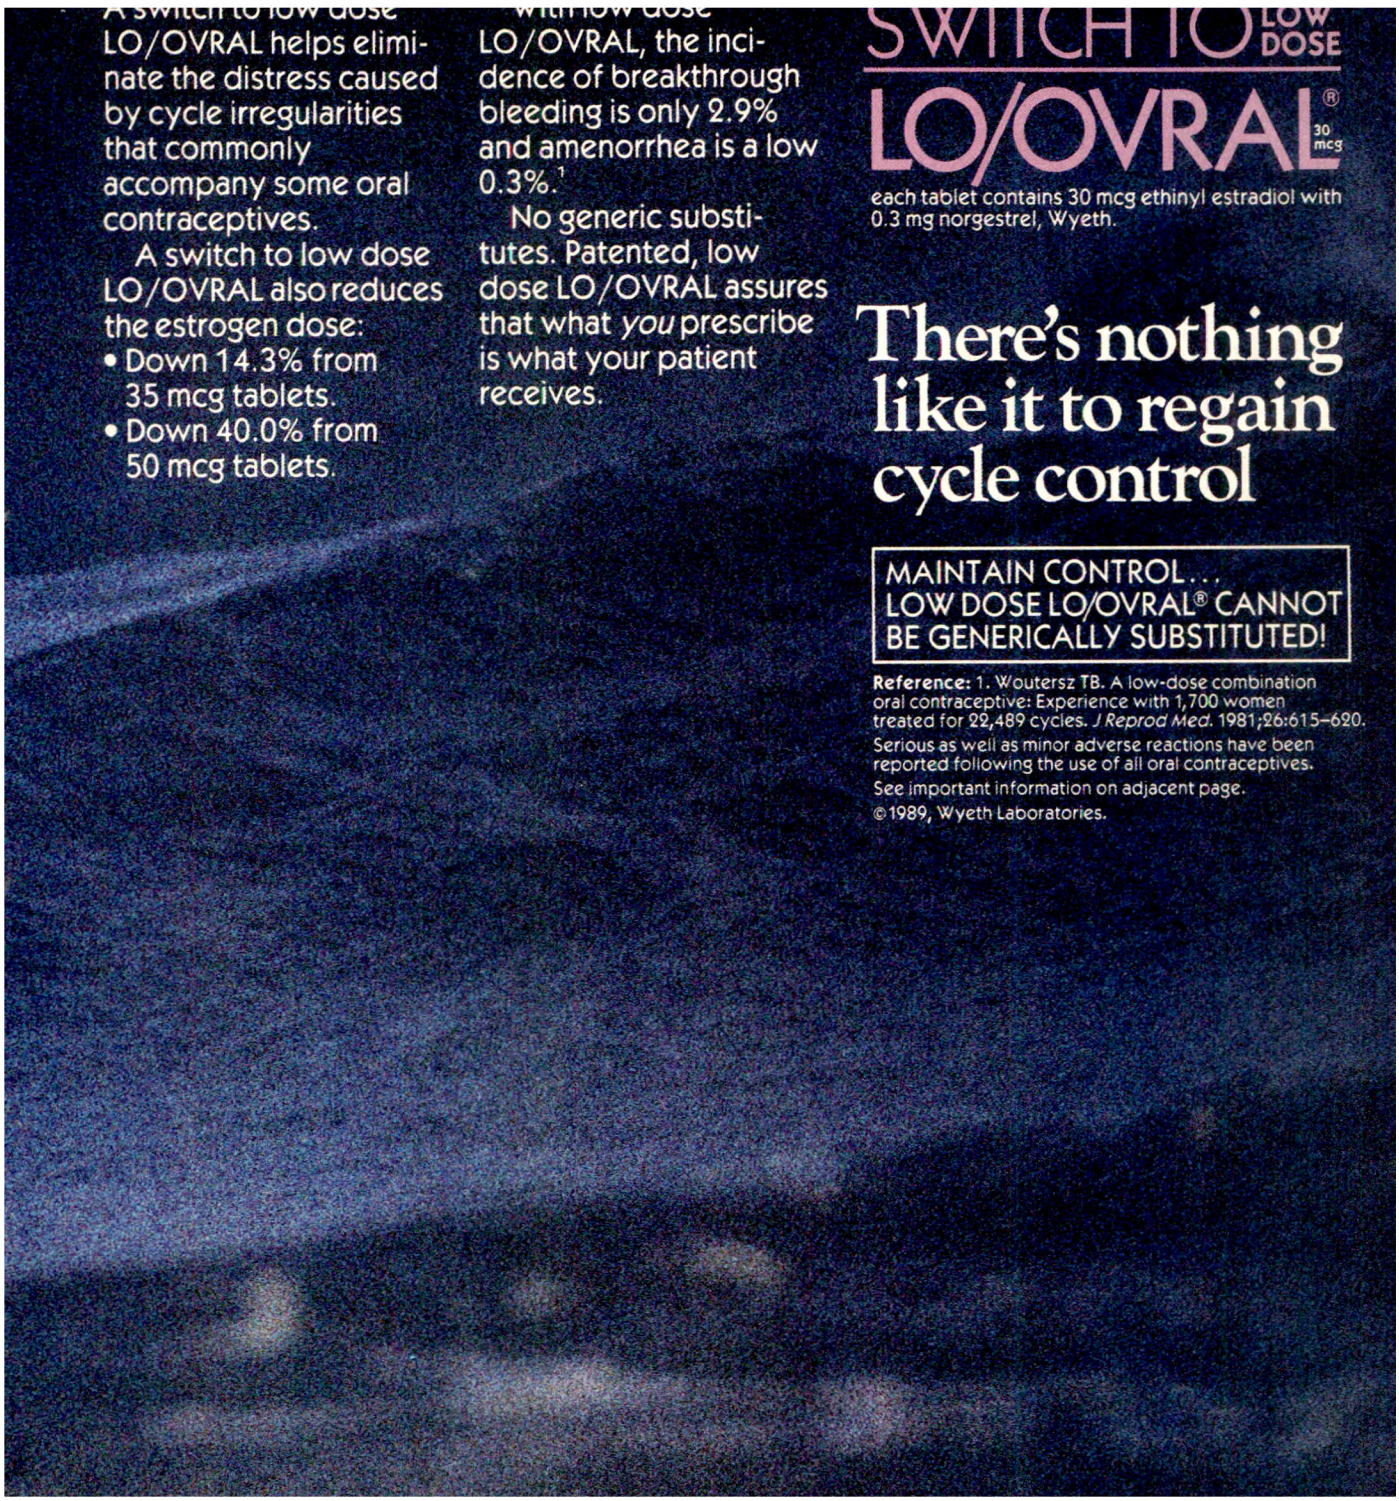
FLR-494-999-03

A 21-year-old female estimated at 42-weeks gestation was admitted for induction of labor. An excellent labor pattern was established within two hours. The cervix was completely effaced and dilated to 5 cms, with the vertex at zero station. Mild to moderate fetal heart rate decelerations on external monitors prompted amniotomy and placement of internal monitors.*

Clinical Status	Monitored Variables	
Admission to labor room—Fetal distress, variable decelerations, and thick meconium were noted at amniotomy. Oxygen administered via nasal cannula at 5 L/min and mother placed in left lateral decubitus position.	BP HR RR Temp	117/72 86/min 14/min 38° C
At 60 minutes—Controlled delivery of a 4100 gram meconium-stained infant. Apgar 7 and 9.		
Immediately after delivery—Mother gasped and became unresponsive.		
Within seconds—ECG, pulse oximetry and automatic blood pressure recordings instituted.	BP HR RR **SpO_2****	73/53 70/min 28/min (shallow) **88%**
At 65 minutes—Mother was intubated and ventilated with 100% oxygen and 10 cm PEEP. 500 ml of crystalloid were infused over 10 minutes.	BP HR RR **SpO_2**	73/51 60/min 0 - Spontaneous 12/min via Ambu bag **91%**
At 85 minutes—Central monitoring begun. PAP = 42/15, CVP = 10, PCWP = 14, CO = 9.4 ABG's obtained: PaO_2 = 76 mmHg, $PaCO_2$ = 47 mmHg, pH = 7.20, SaO_2 (Calc) = 91%.	BP HR **SpO_2**	110/69 90/min **90%**
180 minutes postpartum—Mother transferred to the intensive care unit and remained intubated. FiO_2 = 0.5, PAP = 32/16, CVP = 7, PCWP = 11, CO = 7.7, SaO_2 (Calc) = 89%.	BP HR **SpO_2**	93/57 84/min **91%**
Mother sustained significant physiologic insult as a result of acute amniotic fluid embolization.		
Over the ensuing 96 hours pulmonary function progressively improved and the patient was successfully weaned and extubated.		



*Actual Case Study on file at Nellcor Incorporated. **SpO_2 is the measurement of arterial oxygen saturation by pulse oximetry.



Discussion

This previously healthy labor patient developed a suddenly compromised cardiopulmonary system resulting in hypoxemia that was detected and managed through the early use of a pulse oximeter.

Routine use of a *NELLCOR*® N-200 pulse oximeter to continuously monitor patients during delivery provides for improved patient safety through early warning of respiratory complications.

"Before
switching my pill,
I could bleed
at any time...
or not have a
period at all."

A switch to low dose
LO/OVRAL helps eliminate the distress caused by cycle irregularities that commonly accompany some oral contraceptives.
A switch to low dose LO/OVRAL also reduces the estrogen dose:
• Down 14.3% from 35 mcg tablets.
• Down 40.0% from 50 mcg tablets.
With low dose LO/OVRAL, the incidence of breakthrough bleeding is only 2.9% and amenorrhea is a low 0.3%.[1]
No generic substitutes. Patented, low dose LO/OVRAL assures that what *you* prescribe is what your patient receives.
SWITCH TO LOW DOSE
LO/OVRAL® 30 mcg
each tablet contains 30 mcg ethinyl estradiol with 0.3 mg norgestrel, Wyeth.
There's nothing like it to regain cycle control
MAINTAIN CONTROL...
LOW DOSE LO/OVRAL® CANNOT BE GENERICALLY SUBSTITUTED!

Serious as well as minor adverse reactions have been reported following the use of all oral contraceptives.
See important information on adjacent page.
©1989, Wyeth Laboratories.

IN BRIEF:

Indications and Usage—LO/OVRAL® is indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OC's) as a method of contraception.

Contraindications—OC's should not be used in women with any of the following conditions:

1. Thrombophlebitis or thromboembolic disorders.
2. A past history of deep-vein thrombophlebitis or thromboembolic disorders.
3. Cerebral-vascular or coronary-artery disease.
4. Known or suspected carcinoma of the breast.
5. Known or suspected estrogen-dependent neoplasia.
6. Undiagnosed abnormal genital bleeding.
7. Known or suspected pregnancy (see Warning No. 5).
8. Benign or malignant liver tumor which developed during use of OC's or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems*—An increased risk of thromboembolic and thrombotic disease associated with use of OC's is well established. Three principal studies in Great Britain and 3 in the U.S. have demonstrated increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OC's are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS—In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION (MI)—An increased risk of MI associated with use of OC's has been reported, confirming a previously suspected association. These studies, conducted in the UK, found, as expected, that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of pre-eclamptic toxemia) the higher the risk of developing MI, regardless of whether the patient was an OC user or not. OC's, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to MI) are about twice as likely to have a fatal MI as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal MI compared to users who do not smoke, but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, amount of smoking is also an important factor. In determining importance of these relative risks, however, baseline rates for various age groups must be given serious consideration. Importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; quite likely the same synergistic action exists, but perhaps to a lesser extent.

RISK OF DOSE—In an analysis of data derived from several national adverse-reaction reporting systems, British investigators concluded that risk of thromboembolism, including coronary thrombosis, is directly related to dose of estrogen in OC's. Preparations containing 100 mcg or more of estrogen were associated with higher risk of thromboembolism than those containing 50-80 mcg. Their analysis did suggest, however, that quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the U.S.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES—A large prospective study carried out in the UK estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OC's according to age, smoking habits, and duration of use. Overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), risk being concentrated in older women, in those with long duration of use, and in cigarette smokers. It was not possible, however, to examine interrelationships of age, smoking, and duration of use, nor to compare effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess magnitude of relative risk for this younger group. Available data from a variety of sources have been analyzed to estimate risk of death associated with various methods of contraception. Estimates of risk of death for each method include combined risk of contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OC's) plus risk attributable to pregnancy or abortion in event of method failure. This latter risk varies with effectiveness of method. The study concluded that mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OC's in women over 40 who smoke. Lowest mortality is associated with condom or diaphragm backed up by early abortion. Risk of thromboembolic and thrombotic disease associated with OC's increases with age after about 30 and, for MI, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of pre-eclamptic toxemia, and especially cigarette smoking. Physician and patient should be alert to earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A 4- to 6-fold increased risk of postsurgery thromboembolic complications has been reported in OC users.

If feasible, OC's should be discontinued at least 4 weeks before surgery of a type associated with increased risk of thromboembolism or prolonged immobilization.

PERSISTENCE OF RISK OF VASCULAR DISORDERS—Findings from one study in Britain involving cerebrovascular disease and another in the U.S. concerning MI suggest an increased risk of these conditions in users of OC's persists after discontinuation of the OC's. In the British study, risk of cerebrovascular disease remained elevated in former OC users for at least 6 years after discontinuation. In the U.S. study, increased risk of MI persisted for at least 9 years in women 40- to 49-years-old who had used OC's for 5 or more years. Findings in both studies require confirmation since they are inconsistent with other published information.

2. *Ocular Lesions*—There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with use of OC's. Discontinue OC's if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

3. *Carcinoma*—Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases frequency of carcinoma of the breast, cervix, vagina, and liver. Certain synthetic progestogens, none currently contained in OC's, have been noted to increase incidence of mammary nodules, benign and malignant, in dogs. In humans, 3 case-control studies have reported an increased risk of endometrial carcinoma associated with prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OC's. Of cases found in women without predisposing risk factors (e.g., irregular bleeding at the time OC's were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These are no longer marketed. No evidence has been reported suggesting increased risk of endometrial cancer in users of conventional combination or progestogen-only OC's. Several studies have found no increase in breast cancer in women taking OC's or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women on OC's, found an excess risk in subgroups of OC users with documented benign breast disease. Reduced occurrence of benign breast tumors in users of OC's has been well documented. In summary, there is at present no confirmed evidence from human studies of increased risk of cancer associated with OC's. Close clinical surveillance of all women on OC's is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or with breast nodules, fibrocystic disease, or abnormal mammograms should be monitored with particular care if they elect to use OC's.

4. *Hepatic Tumors*—Benign hepatic adenomas have been found to be associated with use of OC's. One study showed that OC's with high hormonal potency were associated with higher risk than lower potency OC's. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users. Two studies relate risk with duration of use of OC's, the risk being much greater after 4 or more years' use. While hepatic adenoma is rare, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women on OC's. Relationship of these drugs to this type of malignancy is not known.

5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring, and Malignancy in Female Offspring*—Use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have increased risk of developing in later life a form of vaginal or cervical cancer ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence now that OC's further enhance risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OC's. Furthermore, 30 to 90% of such exposed women have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with use of other estrogens, it cannot be presumed they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with use of sex hormones, including OC's, in pregnancy. One case control study estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OC's, hormonal withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some exposures involved only a few days. Data suggest that risk of limb-reduction defects in exposed fetuses is somewhat less than 1 in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OC's. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OC's is unknown. It is recommended that, for any patient who has missed 2 consecutive periods, pregnancy should be ruled out before continuing OC's. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at time of first missed period, and further use of OC's should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and advisability of continuation of the pregnancy should be discussed. It is also recommended that women who discontinue OC's with intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this. The administration of progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease*—Studies report increased risk of surgically confirmed gallbladder disease in users of OC's and estrogens. In one study, increased risk appeared after 2 years' use and doubled after 4 or 5 years' use. In one of the other studies, increased risk was apparent between 6 and 12 months' use.

7. *Carbohydrate and Lipid Metabolic Effects*—Decrease in glucose tolerance has been observed in a significant percentage of patients on OC's. For this reason, prediabetic and diabetic patients should be carefully observed while on OC's. Increase in triglycerides and total phospholipids has been observed in patients on OC's; clinical significance of this finding remains to be defined.

8. *Elevated Blood Pressure*—Increase in blood pressure has been reported in patients on OC's. In some women, hypertension may occur within a few months of beginning OC's. In the 1st year of use, prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. Prevalence in users increases, however, with longer exposure, and in the 5th year of use is 2½ to 3 times the reported prevalence in the 1st year. Age is also strongly correlated with development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure on OC's. Hypertension that develops as a result of taking OC's usually returns to normal after discontinuing the drug.

9. *Headache*—Onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of OC's and evaluation of the cause.

10. *Bleeding Irregularities*—Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing OC's. In breakthrough bleeding, as in all cases of irregular vaginal bleeding, nonfunctional causes should be borne in mind.

In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or change to another OC may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary, since this may increase risk of thromboembolic disease. Women with past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuing OC's. Women with these pre-existing problems should be advised of this possibility and encouraged to use other methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy*—Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast-feeding*—OC's given in the postpartum period may interfere with lactation and decrease quantity and quality of breast milk. Furthermore, a small fraction of the hormones in OC's has been identified in the milk of mothers on OC's; effects, if any, on the breast-fed child have not been determined. If feasible, defer OC's until infant has been weaned.

Precautions—GENERAL—1. A complete medical and family history should be taken prior to initiation of OC's. Pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Pap smear and relevant laboratory tests.

As a general rule OC's should not be prescribed for longer than 1 year without another physical examination.

2. Under influence of estrogen-progestogen preparations, pre-existing uterine leiomyomata may increase in size.

3. Patients with history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while on OC's should stop OC's and use an alternate method to try to determine whether the symptom is drug-related.

4. OC's may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency.

5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence while on OC's. If jaundice develops, OC's should be discontinued.

6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution.

7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. Clinical significance is undetermined.

8. Serum folate levels may be depressed by OC's. Since the pregnant woman is predisposed to development of folate deficiency and incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OC's, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency.

9. The pathologist should be advised of OC therapy when revelant specimens are submitted.

10. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containing OC's: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

Information for the Patient—See Patient Package Labeling.

Drug Interactions—Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.

Carcinogenesis—See Warnings on carcinogenic potential of OC's.

Pregnancy—Category X. See Contraindications, Warnings.

Nursing Mothers—See Warnings.

Adverse Reactions—An increased risk of these serious adverse reactions has been associated with use of OC's (see Warnings): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, benign hepatomas, congenital anomalies.

There is evidence of an association between the following conditions and use of OC's although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients on OC's and are believed to be drug-related: nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally. Gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea, amenorrhea during and after treatment, temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement, and secretion; change in weight (increase or decrease); change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening), intolerance to contact lenses.

The following adverse reactions have been reported in users of OC's, and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, hemolytic uremic syndrome.

Acute Overdose—Serious ill effects have not been reported following acute ingestion of large doses of OC's by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Prophylactic amnioinfusion during labor complicated by meconium: A preliminary report

Yoel Sadovsky, MD, Erol Amon, MD, Mary E. Bade, BSMT, and Roy H. Petrie, MD, ScD
St. Louis, Missouri

The purpose of this prospective and randomized study is to evaluate the safety and efficacy of prophylactic transcervical amnioinfusion in the management of labor complicated by meconium. A preexisting intrauterine pressure catheter was used for amnioinfusion. The incidence of thick meconium was significantly lower after amnioinfusion, compared with standard management (5% versus 62% $p < 0.0005$). This was also demonstrated with spectrophotometry. Significant differences between the amnioinfusion group and the control group were found for the following: arterial cord pH <7.20 (16% versus 38%, $p < 0.05$); meconium more than trace below the vocal cords at delivery (0% versus 29%, $p < 0.05$) and need for positive pressure ventilation at birth (16% versus 48%, $p < 0.05$). No complications related to amnioinfusion were observed. We conclude that (1) transcervical amnioinfusion during labor complicated by meconium is a simple and apparently safe procedure, and that (2) amnioinfusion effectively decreases the frequency of thick meconium, the frequency of neonatal acidemia, the frequency of more than trace meconium below the vocal cords, and the need for positive pressure ventilation. (AM J OBSTET GYNECOL 1989;161:613-7.)

Key words: Amnioinfusion, meconium, meconium aspiration syndrome, labor

Passage of meconium in utero occurs in 8% to 16% of all deliveries.[1-3] Meconium aspiration syndrome occurs in 1% to 3% of all cases of meconium-stained amniotic fluid.[4] The presence of meconium in the amniotic fluid is associated with increased neonatal morbidity and mortality. The mechanism of this association and a cause-effect relationship is still unclear. Although meconium aspiration syndrome is a relatively uncommon complication, this syndrome is a major cause of unexpected neonatal mortality and morbidity. The neonatal mortality associated with this syndrome is as high as 28%.[1,5] Meconium aspiration may occur before labor, during labor, or at delivery. Current methods to prevent meconium aspiration syndrome include the combined obstetric and pediatric approach as described by Carson.[5] This technique includes suctioning of the nasopharynx, mouth, and hypopharynx with a DeLee catheter (ARGYLE, Division of Sherwood Medical Co., St. Louis, Mo.) as soon as the head is born. Immediately after the delivery is completed the pediatrician suctions the oropharynx with a bulb and inspects the vocal cords by direct laryngoscopy. The trachea is directly suctioned if meconium is present at the cords. This technique, which was reported to decrease the frequency of meconium aspiration syndrome, is based on the assumption that meconium aspiration occurs mainly during the delivery process.

The clinical application of transcervical amnioinfusion was first described by Miyazaki and coworkers[6,7] as an intrapartum procedure for the relief of variable decelerations. Later Nageotte and coworkers[8] applied this prophylactic measure to prevent variable decelerations in patients with preterm membrane rupture.

Our hypothesis is that intrapartum dilution of meconium by transcervical amnioinfusion may reduce the risk of meconium aspiration if it occurs during labor or at delivery. It may also improve neonatal outcome. The purpose of this study is to evaluate the safety and efficacy of transcervical amnioinfusion during labor complicated by meconium.

Material and methods

This prospective and randomized study was performed at the three University hospitals of the Department of Obstetrics and Gynecology at Washington University Medical Center. The Human Studies Committee of the medical school approved the study. The patients included women in labor who were found to have more than trace meconium on membrane rupture. Additional inclusion criteria were singleton pregnancy, vertex presentation, ≥34 weeks' gestation, and anticipated time to delivery >1 hour. The exclusion criteria were fetal malpresentation, multiple gestation, fetal malformation, polyhydramnios, chorioamnionitis, cord prolapse, any situation that necessitated urgent

intervention, and maternal heart disease classified as New York Heart Association's class II or greater.

Informed consent was obtained before each patient was randomly assigned to an amnioinfusion or a control group. Randomization was carried out with sealed envelopes. The control group received standard labor management without amnioinfusion. In the amnioinfusion group a normal saline solution was connected through a Y-set to an existing intrauterine pressure catheter. The infused saline solution was continuously warmed to 37° C. The initial infusion was 600 ml during the first hour, then 180 ml/hr. The amnioinfusion was stopped before delivery. All patients had continuous internal fetal monitoring. The combined obstetric-pediatric suctioning approach to prevent meconium aspiration was used in all deliveries.

Samples of the meconium-stained fluid were aspirated through the pressure catheter, whenever possible, before and after the amnioinfusion. Meconium concentration, as measured by spectrophotometry, was used as an index of meconium thickness. The spectrophotometric determination was a modification of the method of Molcho et al.[9] Samples were frozen at −20° C. For meconium thickness determination the samples were brought to room temperature, vortexed for 60 seconds, and centrifuged at 1000 rpm for 5 minutes. Any sample that contained thick meconium was diluted with distilled water. Absorption readings were recorded by spectrophotometry, and compared with a distilled water control at 340 to 500 nm. The absorbance measurements were then plotted on linear graph paper, and the "background" absorbance line of nonstained amniotic fluid was determined. The "expected" optical density (OD) is the point on the drawn line that intersects with the 410 nm wavelength. The Δ OD 410 was calculated as the difference between the

measured OD and the expected OD at this wavelength. The Δ OD 410 value is the absorbance contributed by meconium.

Neonatal outcome was assessed by pediatricians who were unaware of the group to which each patient was allocated. The independent two-tailed Student t test, χ^2 test, and Fisher's exact test, when appropriate, were used for statistical analysis. Significance was set at $p < 0.05$.

Results

These data were collected between December 1987 and September 1988. A total of 40 patients were enrolled in the study; 19 were randomly assigned to the amnioinfusion group, and 21 were assigned to the control group. Table I compares demographic characteristics for the two groups. Antepartum risk factors were present in 12 patients. This included four patients with chronic hypertension, two in each group; three patients with mild preeclampsia, two in the control group and one in the amnioinfusion group; five patients with post dates, three in the control group and two in the amnioinfusion group. One patient in each group underwent a trial of labor after a previous cesarean section. Various clinical characteristics of labor are compared in Table II. No significant differences were found.

In the group that underwent amnioinfusion, a mean volume of 1357 ml (range, 700 to 2750 ml) of fluids was infused over a mean period of 6½ hours (range, 2 to 12½ hours). There were no procedure-related complications during this study.

Outcome data were compared between the group that underwent amnioinfusion and the control group. The frequency of thick meconium at initial evaluation was 62% in the control group and 79% in the amnioinfusion group (p = NS). After amnioinfusion the frequency of thick meconium remained at 62% for the control group, whereas it decreased to 5% ($p < 0.0005$) in the amnioinfusion group. Fig. 1 demonstrates the sepectrophotometric measurements for 11 of the 19 patients who underwent amnioinfusion from whom samples were obtained before and after the amnioinfusion. The mean Δ OD 410 value was significantly reduced from 0.526 ± 0.29 to 0.201 ± 0.17 after amnioinfusion in these 11 patients ($p < 0.005$). A total of 95% of the patients in both groups had a reactive fetal heart rate on admission. Before the second stage of labor 95% of the patients who underwent amnioinfusion had a reactive tracing versus 81% of the control group (p = NS). The percentage of patients with variable decelerations increased from 24% to 57% as labor progressed in the control group, whereas the percentage of patients with variable decelerations remained at 37% in the group that underwent amnioinfusion (p = NS).

Table III gives the mode of delivery of both groups. Of note is the observation that two cesarean sections were performed because of fetal distress, both in the control group. Postpartum fever occurred in two patients in the group that underwent amnioinfusion, both after cesarean section. In the control group five patients had postpartum fever, and of these, three were delivered of infants by cesarean section. Endometritis occurred in three patients. In each case endometritis followed cesarean section, two in the group subjected to amnioinfusion and one in the control group. The incidence of 1-minute Apgar scores <4 did not differ significantly between the amnioinfusion and the control groups (5% versus 9%, respectively). Similarly, no difference was found for the incidence of 5-minute Apgar scores <7 (5% in both groups).

Umbilical arterial cord blood analyses are shown in Fig. 2. A significantly lower rate of neonatal acidemia is noted in the group that underwent amnioinfusion ($p < 0.05$). Meconium, in any degree, was found below the vocal cords in 20% of all newborns. Fig. 3 compares the incidence of meconium below the cords, classified by pediatricians as greater than "trace." This occurred in 29% of newborns in the control group, and 0% in the group subjected to amnioinfusion ($p = 0.01$). Every newborn underwent suctioning with the DeLee catheter and direct laryngoscopy for the management of

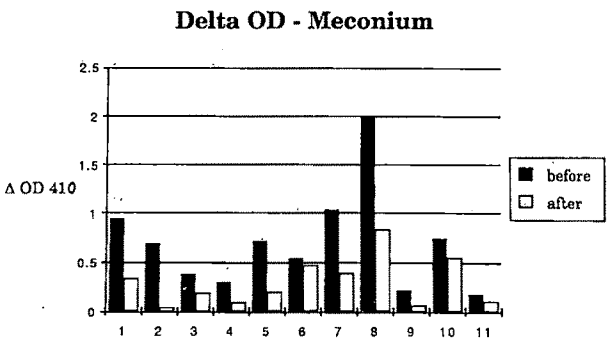

Fig. 1. Spectrophotometric measurements of meconium concentration in amniotic fluid in 11 patients before and after amnioinfusion. *OD* = optical density.

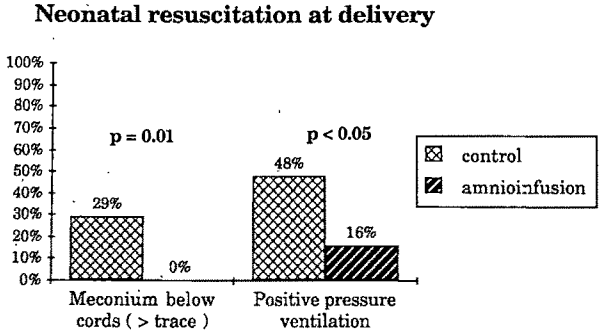

Fig. 3. Comparison of meconium below the vocal cords and need for resuscitation at birth between control and amnioinfusion groups.

delivery complicated by meconium. As shown in Fig. 3, 48% of newborns in the control group also needed positive pressure ventilation. This was significantly greater than the 16% in the group that underwent amnioinfusion ($p < 0.05$). No newborn required cardiac or pharmacologic resuscitation, and none left the delivery room intubated. No newborn had meconium aspiration syndrome. One infant in the control group had transient respiratory distress of unclear cause and required oxygen support for 24 hours.

Comment

Several investigators have emphasized the risk of meconium aspiration occurring during the newborn's first few breaths, and the benefit from the combined obstetric-pediatric resuscitation approach.[3, 5, 10] Davis et al.[2] and later Falciglia[11] have shown that meconium aspiration syndrome may still occur despite appropriate use of the combined approach described by Carson. This occurrence may represent intrauterine meconium aspiration, which may have occurred before labor or during labor. Several studies have provided evidence that suggests the occurrence of fetal meconium aspiration.[4, 12-14] We adopted the technique of amnioinfusion as described by Miyazaki and coworkers[7] and modified by Nageotte[8] in an attempt to improve the outcome for fetuses exposed to meconium during labor.

The following conclusions can be drawn from our preliminary findings. First, transcervical amnioinfusion during labor complicated by meconium is a simple procedure that carries no apparent increase in maternal and neonatal morbidity. Second, amnioinfusion was significantly effective in the dilution of meconium-stained amniotic fluid. Third, amnioinfusion during labor complicated by meconium improved neonatal outcome as demonstrated by: (1) a significant decrease in the frequency of neonatal acidemia, (2) a significant reduction in the frequency of greater than "trace" meconium below the newborn's vocal cords, and (3) the reduction in need for positive pressure ventilation during resuscitation at birth.

We propose that the observed improvement in neonatal outcome is achieved by mechanical dilution of meconium during labor, which decreases the risk of intrapartum aspiration of thick and tenacious meconium. The increased risk of meconium aspiration syndrome when thick meconium is present early in labor has been previously suggested by Meis.[15] Furthermore, a decrease in the incidence of fetal acidemia during labor may decrease the frequency of fetal gasping,[13, 14] and thus the absence of acidemia may prevent the passage of meconium into the deeper airways.[12, 16] In the fetal lamb, asphyxia induced by temporary occlusion of the umbilical cord caused gasping and a change in tracheal pressure to −75 mm Hg for more than 1 second. In these circumstances, >10 ml of viscous amniotic fluid contaminated with meconium can be inhaled into the tracheobronchial tree.[16] Obviously, transcervical amnioinfusion will not prevent meconium aspiration that may have occurred before the onset of labor.

Although meconium aspiration syndrome is a leading cause of unanticipated neonatal mortality and mor-

bidity among term infants, this syndrome is a relatively uncommon complication. More patients will be needed to definitively study the effects of amnioinfusion on the syndrome. Power calculations reveal that >750 patients in each group will be needed to detect a reduction in the frequency of meconium aspiration syndrome from an incidence of 3% to 1% ($\alpha = 0.05$ and $\beta = 0.20$). Despite the small number of patients in this study we were able to demonstrate beneficial effects of amnioinfusion. The observed reduction in relative fetal-neonatal acidemia and the quantity of meconium below the vocal cords are two factors thought to be closely related to the development of meconium aspiration syndrome.

It is unclear whether the observed reduction of relative acidemia in the group that underwent amnioinfusion is due to mechanical dilution of the meconium or some other mechanism. It is possible that the relative sparing of umbilical cord compression by amnioinfusion lessens the frequency of variable decelerations as labor progresses, and thus contributes to an improved acid-base status. Perhaps amnioinfusion ameliorates yet unknown factors involved in the pathogenesis of meconium-related complications.

Collection of further data with this technique may assist investigators in the evaluation of the risk of meconium aspiration before labor. The association between meconium thickness and the incidence and severity of meconium aspiration may be studied in greater detail.

Lack of evidence of a vasodepressor role for relaxin in spontaneously hypertensive and normotensive pregnant rats

Robert A. Ahokas, PhD, Baha M. Sibai, MD, and Garland D. Anderson, MD
Memphis, Tennessee

To test the possibility that the ovarian polypeptide hormone relaxin mediates the vasodepressor effect of pregnancy, we measured changes in blood pressure in three groups of spontaneously hypertensive and Wistar-Kyoto normotensive rats: (1) pregnant, bilaterally oophorectomized rats on postmating day 13, (2) pregnant, sham-oophorectomized rats on postmating day 13, and (3) nonpregnant, sham-oophorectomized rats after 13 days. The day before parturition we also measured the pressor responsiveness to angiotensin II and norepinephrine. Systolic blood pressure fell significantly during the last week of gestation in both strains, reaching normotensive levels in the hypertensive rats by term. The pressor responsiveness to angiotensin II, but not norepinephrine, of the pregnant rats was reduced compared with that of the nonpregnant rats in both strains. Oophorectomy did not prevent the fall in blood pressure or the decrease in vascular reactivity to angiotensin II. Therefore, although ovarian relaxin secretion increases during pregnancy, it apparently does not decrease vascular sensitivity to angiotensin II or cause vasodilation. (AM J OBSTET GYNECOL 1989;161:618-22.)

Key words: Blood pressure, relaxin, pregnancy, angiotensin II, spontaneously hypertensive rat

Maternal cardiac output increases and total peripheral vascular resistance decreases during normal pregnancy in both humans and laboratory rats.[1] Pregnancy has a profound antihypertensive effect in hypertensive animals such as the spontaneously hypertensive rat. During the last third of gestation, blood pressure falls progressively and usually reaches normotensive levels by parturition.[2-4] The exact mechanism that causes these decreases is not known, but it is widely believed that a relative insensitivity to the pressor effects of angiotensin,[5] perhaps mediated by prostanoids,[6] may be involved. Recently a long-term vasodepressor action of relaxin, an ovarian polypeptide hormone produced in large amounts during pregnancy, has been described.[7] In addition, the pregnancy-associated decrease in blood pressure in humans[8] and in rats[9] coincides with increased circulating levels of relaxin. Long-term relaxin infusion blunts the in vitro vasoconstrictor responses of various vascular beds to arginine vasopressin and norepinephrine in spontaneously hypertensive rats,[10] similar to the responses observed in near-term pregnant spontaneously hypertensive rats.[11] Together these observations suggest that relaxin may play a role in the attenuation of vascular responsiveness to pressor agents and the reduction in blood pressure during normal pregnancy. This study was undertaken to determine if the removal of the source of endogenous relaxin (bilateral oophorectomy) would prevent the normal fall in blood pressure and the decrease in pressor responsiveness to vasoconstrictors during the last week of pregnancy in spontaneously hypertensive rats and normotensive Wistar-Kyoto rats.

Material and methods

Female spontaneously hypertensive rats and Wistar-Kyoto rats, 15 to 20 weeks old (Harlan Laboratories, Inc., Indianapolis) were housed at 23 ± 1° C and a 12:12 hour light-dark cycle (with lights on from 7 AM to 7 PM), and fed Purina rodent chow (Ralston Purina, St. Louis) as desired with tap water to drink. For breeding, the females were caged with mature male breeders (1:1) of the same strain, and vaginal smears were checked daily in the morning for the presence of spermatozoa. Timed-pregnant females were then housed one per cage throughout pregnancy. Systolic blood pressure was measured weekly through the first 2 weeks of pregnancy and semidaily during the last week of pregnancy by means of tail-cuff plethysmography (IITC, Inc., Woodland Hills, Calif.). Since the corpus luteum is the exclusive source of relaxin in the rat,[9] bilateral oophorectomy was used to prevent the increased endogenous relaxin secretion. On day 13 of gestation the rats were anesthetized with methoxyflurane and a midline laparotomy was performed. Both

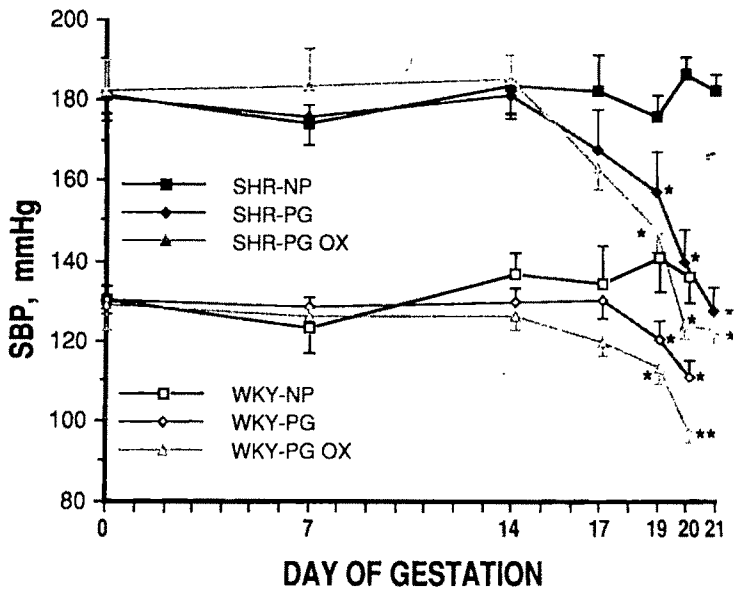

Fig. 1. Changes in systolic blood pressure *(SBP)* in nonpregnant and pregnant, spontaneously hypertensive *(SHR)* and normotensive Wistar-Kyoto *(WKY)* rats. Data plotted as mean ± SEM. *NP*, Nonpregnant, sham-oophorectomized; *PG*, pregnant sham-oophorectomized; *PG OX*, pregnant, bilaterally oophorectomized. *Asterisk* indicates significant difference from *NP* of same strain ($p \leq 0.05$); *double asterisk* indicates significant difference between *PG* and *PG OX* of same strain ($p \leq 0.005$).

ovaries were removed after ligation of the ovarian vessels ($n = 9$ spontaneously hypertensive rats; $n = 7$ Wistar-Kyoto rats). In other rats the ovaries were only visualized (sham-oophorectomized) ($n = 8$ spontaneously hypertensive rats; $n = 8$ Wistar-Kyoto rats). Nonpregnant females of each strain ($n = 8$ spontaneously hypertensive rats; $n = 7$ Wistar-Kyoto rats) were also sham oophorectomized after 13 days. Pregnancy was maintained in the oophorectomized rats by daily subcutaneous injection of 200 ng 17β-estradiol and 3 mg progesterone in 0.1 ml sesame oil. Both pregnant and nonpregnant sham-oophorectomized rats received 0.1 ml sesame oil only.

The day before expected delivery (postmating day 21 for spontaneously hypertensive rats; postmating day 20 for Wistar-Kyoto rats) whole-body pressor responsiveness to angiotensin II and norepinephrine were measured. Catheters had been placed in the left carotid artery (for blood pressure measurement) and the right jugular vein (for vasoconstrictor infusion) the previous day. For these measurements, the rat was placed in a Plexiglas restrainer cage. The arterial catheter was connected to a Statham P23Gb strain-gauge pressure transducer, and blood pressure was recorded continuously on a Gould 2200S physiologic recorder (Gould, Inc., Cleveland). After blood pressure stabilization (approximately 30 minutes), mean blood pressure responses to bolus injections of angiotensin II (5 to 2000 ng/kg, intravenously) and norepinephrine (10 to 4000 ng/kg, intravenously) were measured. Each dose was contained in a volume of 50 μl and was flushed into the catheter with 0.2 ml of normal saline solution. Blood pressure was allowed to return to baseline between each dose; a 1-hour recovery period was allowed between pressor substances. Dose-response curves for each pressor substance were generated from the maximum change in mean arterial pressure at each dose. Maximum effect was estimated as the intercept of the linear regression line of the double reciprocal plot of dose and maximum blood pressure responses. The 50% effective dose of each pressor substance was determined by log dose-probit analysis.[12]

The data were analyzed statistically by means of two-factor analysis of variance. Significant differences between means were determined by the least-squares means method. Values of $p \leq 0.05$ were considered statistically significant for all analyses.

Results

At conception systolic blood pressure of the spontaneously hypertensive rats was significantly higher than that of the Wistar-Kyoto rats (Fig. 1). During the last week of gestation, systolic blood pressure of both the sham-oophorectomized and the bilaterally oophorectomized spontaneously hypertensive rats decreased progressively and was significantly lower than that of the nonpregnant spontaneously hypertensive rats by day 19. Furthermore, the systolic blood pres-

sure of both the oophorectomized and the sham-oophorectomized pregnant spontaneously hypertensive rats was not significantly higher than that of the nonpregnant normotensive Wistar-Kyoto rats by day 19. There were no significant differences in systolic blood pressure between oophorectomized and sham-oophorectomized spontaneously hypertensive rats at any time during gestation. The systolic blood pressure of pregnant normotensive Wistar-Kyoto rats also fell, although not as much as in the spontaneously hypertensive rats, during the last week of gestation and was significantly lower than that of the nonpregnant rats by day 19. Systolic blood pressure of the oophorectomized pregnant Wistar-Kyoto rats, unlike spontaneously hypertensive rats, was significantly lower than that of the sham-oophorectomized pregnant Wistar-Kyoto rats on day 20.

The angiotensin II dose–pressor response curves for both the oophorectomized and sham-oophorectomized pregnant rats were shifted to the right of the curves for the nonpregnant rats, in both the spontaneously hypertensive rats (Fig. 2, *A*) and Wistar-Kyoto rats (Fig. 2, *B*). The angiotensin II 50% effective dose and maximum effect were significantly higher in both groups of pregnant spontaneously hypertensive rats compared with the nonpregnant spontaneously hypertensive rats (Table I). In the normotensive Wistar-Kyoto rats, only the angiotensin II 50% effective dose was significantly increased in the pregnant rats in comparison with the nonpregnant rats. In addition, the angiotensin II dose-response curves for the normotensive Wistar-Kyoto rats were shifted to the right of those of the spontaneously hypertensive rats with a significantly higher angiotensin II 50% effective dose.

The norepinephrine dose-response curves of the pregnant spontaneously hypertensive rats (Fig. 3, *A*) and Wistar-Kyoto rats (Fig. 3, *B*) were similar to those of the nonpregnant rats of each strain. There were no significant differences in the norepinephrine 50% effective dose or maximum effect (Table I).

Comment

In the rat, as in humans, pregnancy is accompanied by a decrease in total peripheral vascular resistance and blood pressure. Although the mechanism causing vasodilation is not entirely understood, it is widely believed that attenuation of resistance vascular sensitivity to endogenous pressor substances such as angiotensin II plays a central role. Results of our study confirm those of Massicotte et al.[13] that whole-body pressor responsiveness to angiotensin II is reduced in term-pregnant spontaneously hypertensive rats and Wistar-Kyoto rats in relation to nonpregnant rats (Fig. 2, Table I). However, we cannot state with certainty that the refractoriness of the vascular response to angiotensin II is the cause of the decrease in blood pressure. Whole-body pressor responsiveness to norepinephrine in term-pregnant rats was not significantly different from that of nonpregnant rats in either strain (Fig. 3, Table I).

Increased plasma levels of relaxin are also associated with the decrease in blood pressure during pregnancy in the rat[9] and in humans.[8] The primary function of relaxin is apparently to relax the uterus and pubic symphysis and to soften the cervix.[14] Recently, however, relaxin has been observed to also have a vasodepressor action in the rat. Long-term intravenous infusions of homologous relaxin in cycling nonpregnant spontaneously hypertensive rats markedly lowered systolic

blood pressure,[7] and blunted the constrictor response to arginine vasopressin and norepinephrine in the perfused mesenteric vasculature.[10] The dose-response curves were nearly identical to those obtained from the perfused mesenteric vascular beds of 20- to 21-day-pregnant spontaneously hypertensive rats.[11] These results suggested that relaxin may be one of the circulating factors responsible for the decrease in vascular sensitivity to circulating vasoconstrictor hormones and blood pressure during pregnancy. However, when we prevented the pregnancy-associated increase in endogenous relaxin in both spontaneously hypertensive rats and normotensive Wistar-Kyoto rats by removing the ovaries on day 13 of gestation, systolic blood pressure fell normally during the last week of gestation (Fig. 1), and the in vivo vascular reactivity to exogenous angiotensin II was attenuated to the same degree as in pregnant sham-oophorectomized rats at term (Fig. 2, Table I), suggesting that relaxin does not have a vasodepressor effect. An alternative explanation for these results is that other tissues may produce and secrete relaxin during pregnancy (relaxin is produced by the placenta in rabbits and horses, and by the endometrium in guinea pigs.[14]). Although we did not measure plasma relaxin concentration at the end of the experiment because of our lack of a homologous radioimmunoassay for rat relaxin, this explanation is not likely. It has been conclusively shown that the corpus luteum is the only tissue that produces relaxin in the rat; and plasma relaxin immunoactivity falls rapidly to prepregnant levels with a mean clearance half-life of approximately 1 hour after bilateral ovariectomy on day 21 of pregnancy.[9] Another alternative is that the ovaries may not have been entirely removed in our study. Some corpus luteum tissue may have remained and continued to produce and secrete relaxin. This also is unlikely because

great care was taken to ligate the ovarian vessels proximal to the ovaries, and both the ovaries and surrounding fat were excised. Careful inspection at the end of the experiment revealed no trace of ovarian tissue.

Although removal of the ovaries did not prevent the normal decrease in vascular reactivity and blood pressure associated with pregnancy, the factor(s) involved in these cardiovascular adaptations may nevertheless be of ovarian origin. Plasma levels of 17β-estradiol and progesterone increase throughout pregnancy, and recent evidence has shown that 17β-estradiol infusion (although not progesterone), produced significant systemic vasodilation[15] and suppressed the pressor responses to angiotensin II in nonpregnant oophorectomized ewes.[15, 16] Our results in rats indirectly support this observation. We maintained pregnancy in the oophorectomized rats by daily injection of pharmacologic doses of 17β-estradiol and progesterone. Blood pressure in the oophorectomized pregnant Wistar-Kyoto rats decreased even more than that of sham-oophorectomized pregnant rats and reached statistical significance by the day before delivery. This suggests that one or both steroids may induce vasodilation in a dose-dependent manner, but additional work is necessary to substantiate this possibility.

We thank Ed B. Cannon for technical assistance and Kristopher Arheart for assistance in statistical analysis of the data.

Perinatal factors influencing atrial natriuretic peptide levels in umbilical arterial plasma at the time of delivery

Lony C. Castro, MD, Chander P. Arora, PhD, Kay E. Roll, RN, Deborah A. Sassoon, MD, and Calvin J. Hobel, MD

Los Angeles, California

Little is known about atrial natriuretic peptide metabolism or secretion in the human fetus. The purpose of this study was to determine if both the placenta and umbilical vessels are possible sites of atrial natriuretic peptide metabolism and to evaluate the effects that labor, route of delivery, prolonged pregnancy, preeclampsia, and fetal distress have on umbilical arterial atrial natriuretic peptide levels. We found that plasma atrial natriuretic peptide levels in the umbilical artery are significantly greater than those in the vein ($p < 0.001$). Umbilical arterial and umbilical venous atrial natriuretic peptide levels were higher in plasma samples collected immediately at delivery when compared with those obtained 10 minutes later ($p < 0.001$). Umbilical arterial atrial natriuretic peptide levels were elevated in pregnancies complicated by preeclampsia and fetal distress ($p < 0.01$). Labor, route of delivery, and prolonged pregnancy had no effect on umbilical arterial atrial natriuretic peptide levels. We propose that both the placenta and umbilical vessels contain atrial natriuretic peptide receptors that are involved in the clearance or metabolism of atrial natriuretic peptide. The increased umbilical arterial atrial natriuretic peptide levels present in preeclampsia and fetal distress may reflect an attempt by the fetus to regulate blood flow. (AM J OBSTET GYNECOL 1989;161:623-7.)

Key words: Atrial natriuretic peptide, umbilical artery, fetal distress

Atrial natriuretic peptide (ANP) refers to a family of peptides secreted by the heart that are involved in the regulation of blood pressure and blood volume through a variety of effects on the cardiovascular, renal, and endocrine systems.[1] The major stimulus for ANP release appears to be atrial distension, but neural and humoral factors,[2, 3] as well as alterations in myocardial work,[4] may also modulate ANP secretion. ANP is cleared rapidly from the circulation of adults probably by binding to specific receptors located in many vascular beds.[5, 6] There is also evidence for a much slower degradation of ANP, possibly by a circulating peptidase.[7]

ANP has been identified in the fetal heart and circulation of a number of mammalian species. The ovine fetus has been the most intensively studied and has been shown to respond to infused ANP with an increase in urine output, as well as a decrease in blood pressure and blood volume.[8] Two seemingly disparate stimuli, intravascular volume expansion and acute hypoxia with accompanying volume depletion, have been shown to stimulate ANP release in fetal sheep.[9, 10] Under basal conditions, ovine fetal plasma ANP levels have been shown to be higher than maternal levels. Experiments demonstrating that fetal plasma ANP clearance rates exceed maternal rates suggest that the high baseline fetal levels are due to an increase in the secretion of ANP by the fetus.[11]

Little is known about the metabolism or secretion of ANP in the human fetus. The possibility that the placenta may be a site of ANP clearance or metabolism is suggested by a recent report documenting the presence of ANP receptors on the fetal side of the placenta.[12] An umbilical arterial-venous difference in ANP levels has also been reported by one group but this has not been confirmed by others.[13, 14] Information about possible stimuli for ANP secretion in the human fetus is also limited. However, one can postulate that relatively common conditions such as advanced gestational age, preeclampsia, and fetal distress, which may be associated with hypoxia or alterations in the fetal cardiovascular system and hormonal environment, could affect fetal ANP secretion.

The purpose of this study was to determine if both the placenta and umbilical vessels are possible sites of ANP clearance or metabolism and to determine if a circulating peptidase with the capability of degrading ANP is present in the umbilical placental circulation. We also attempted to evaluate the effects that prolonged pregnancy, preeclampsia, and fetal distress have

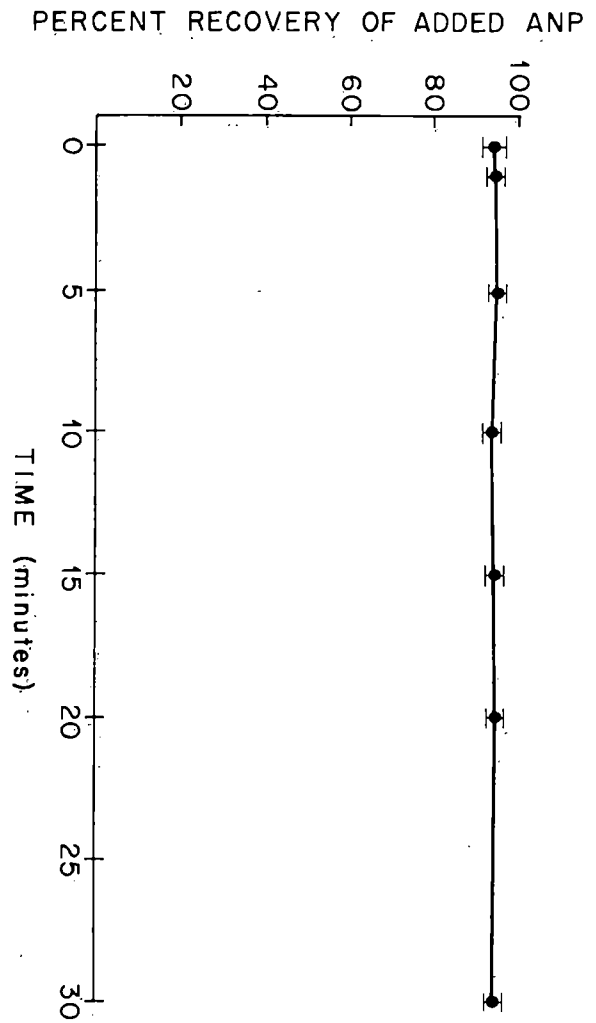

Fig. 1. Amount of ANP (expressed as percent of recovery of added ANP) in umbilical plasma incubated at 37° C for up to 30 minutes.

on umbilical arterial ANP levels at the time of delivery. Because labor and route of delivery could have confounding effects on the above variables, their influence on umbilical arterial ANP levels was also examined.

Material and methods

ANP metabolism by the placenta and umbilical vessels. To evaluate placental ANP metabolism, 165 paired umbilical arterial and umbilical venous blood samples were collected from double-clamped umbilical cords immediately at the time of delivery. To evaluate the possibility of ANP metabolism in the umbilical vessels, paired umbilical arterial (n = 65) or umbilical venous (n = 61) blood samples were collected. The first sample was obtained from a double-clamped umbilical cord immediately at delivery and the second was obtained approximately 10 minutes after delivery (range 9 to 12 minutes).

ANP degradation by a circulating peptidase. Umbilical arterial and venous blood was collected at the time of delivery in tubes containing ethylenediaminetetraacetic acid (1.0 mg/ml), pooled, and centrifuged at 2000 g for 10 minutes at 4° C. ANP (260 pg/ml) was added to the plasma and the plasma was incubated at 37° C. Aliquots of plasma were then removed, extracted, and assayed for ANP after 0, 1, 5, 10, 15, 20, and 30 minutes of incubation. Each incubation study used the pooled umbilical plasma samples from four patients, and 16 patients were studied in a total of four separate incubations.

Table I. ANP levels at delivery and 10 minutes after delivery

Samples	*ANP (pg/ml) (mean ± SEM)*	*p Value*
At delivery (n = 165)		<0.001
Umbilical artery	98 ± 15	
Umbilical vein	56 ± 9	
Umbilical artery (n = 65)		<0.001
At delivery	80 ± 14	
10 min after delivery	45 ± 9	
Umbilical vein (n = 62)		<0.001
At delivery	45 ± 8	
10 min after delivery	31 ± 4	

Selection of patient groups. Umbilical arterial cord blood was collected for ANP from a double-clamped cord within 1 minute of delivery in five groups of patients.

Group 1: Normal controls. Nineteen patients with gestational ages from 37 to 40 weeks had spontaneous vaginal deliveries. None of the pregnancies had any antenatal, intrapartum, postpartum, or neonatal complications. Birth weights ranged from 2880 to 3729 gm and all 1- and 5-minute Apgar scores were ≥8. The only medications administered during labor or delivery were epidural or local anesthetics.

Group 2: Elective cesarean section. Ten patients between 37 and 40 weeks' gestation were delivered by elective cesarean section without labor. Eight were repeat cesarean sections and two were done because of breech presentations. As in the normal control group, this group had no complications. Birth weights ranged from 3345 to 4000 gm. All 1- and 5-minute Apgar scores were ≥8. All patients had epidural anesthesia for delivery.

Group 3: Prolonged pregnancies. Twenty-one patients were delivered between 41 and 43 weeks' gestation. Medications administered in labor included fentanyl and Pitocin, as well as epidural anesthesia. Patients in this group had either vaginal or cesarean section deliveries. All had normal fetal heart rate tracings during labor with the exception of three patients with fetal heart rate tracings showing either severe variable or repetitive late decelerations. Each of these patients had umbilical arterial pH values at delivery that were >7.25.

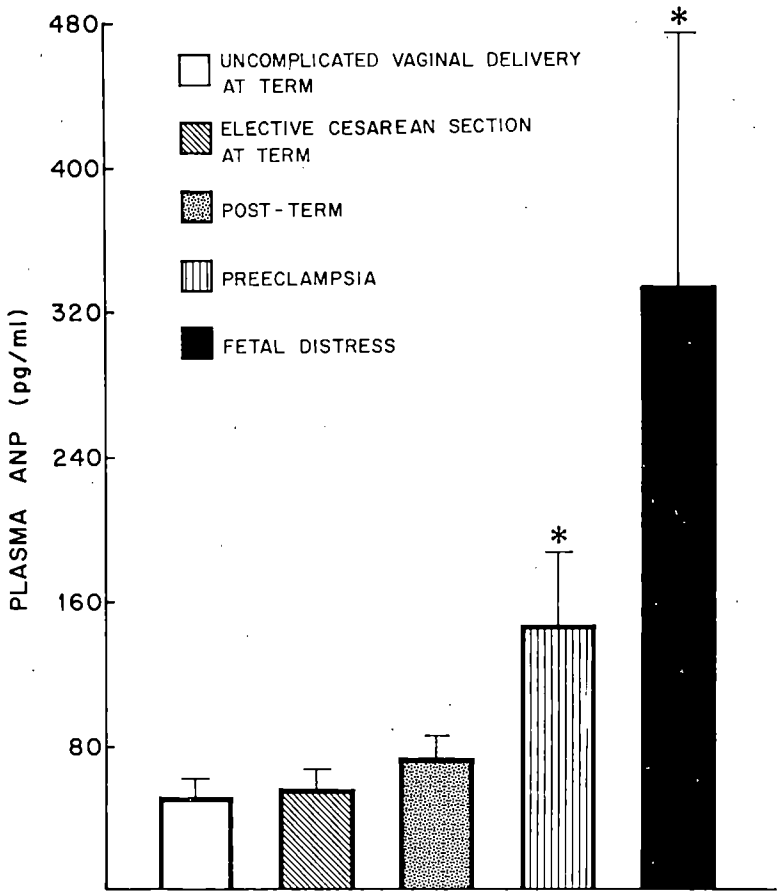

Fig. 2. Umbilical arterial ANP levels in different groups studied. *Asterisk,* $p < 0.01$ versus uncomplicated vaginal delivery at term.

All 1- and 5-minute Apgar scores were ≥7. Birth weights ranged from 2800 to 4200 gm and there were no neonatal complications.

Group 4: Preeclampsia. Eight patients between 27 and 42 weeks' gestation were delivered with a diagnosis of preeclampsia according to the criteria of the American College of Obstetricians and Gynecologists.[15] Three had mild preeclampsia and five had severe preeclampsia. Blood pressures before delivery ranged from 140/85 to 160/110 mm Hg and qualitative urine protein levels obtained from catheterized urine specimens ranged from 2+ to 4+. None of the patients had a history of chronic hypertension or renal disease. All patients received magnesium sulfate and one received hydralazine before delivery. Five had cesarean sections and three were delivered vaginally. Six of these patients had regional anesthesia for delivery and one received general anesthesia. All but one of the patients had normal fetal heart rate tracings. This fetal heart rate tracing showed a tachycardia with decreased variability. The umbilical arterial pH at delivery was 7.32. The neonate was born to a mother with severe preeclampsia at 27 weeks' gestation and had 1- and 5-minute Apgar scores of 3 and 8. This neonate subsequently died of severe respiratory distress and prematurity. The remaining seven neonates had 1- and 5-minute Apgar scores that were ≥8. Neonatal complications included two neonatal deaths—one caused by respiratory distress as noted and one caused by congenital cytomegalovirus pneumonia.

Group 5: Fetal distress. Ten patients delivered between 31 and 42 weeks' gestation had abnormal fetal heart rate tracings during labor (either severe variable decelerations, repetitive late decelerations, prolonged bradycardias, and/or tachycardias with decreased variability). Each of these was associated with an umbilical arterial pH at delivery ≤7.20 (range 6.85 to 7.20), with the exception of one fetus for whom an umbilical blood gas value was not obtained but whose scalp blood pH just before delivery was 7.20. Six of these patients were delivered by cesarean section and four had vaginal deliveries. One-minute Apgar scores ranged from 3 to 8 and all 5-minute Apgar scores were ≥8. Neonatal complications included one neonatal death attributed to asphyxia and probable sepsis.

Blood collection, plasma extraction, and ANP radioimmunoassay. All blood, with the exception of that used for the ANP degradation studies, was collected in

chilled test tubes containing ethylenediaminetetraacetic acid (1.0 mg/ml) and aprotinin (500 kallikrein inhibitor units per milliliter). The blood was centrifuged at 2000 *g* for 10 minutes at 4° C. The procedures we used for the plasma extractions and ANP radioimmunoassay have been previously described in detail.[16] In brief, the plasma was extracted under acidic conditions on C-18 Sep Pak columns (Waters Associates, Milford, Mass.). ANP was measured with a double-antibody radioimmunoassay with antihuman ANP (99-126) obtained from Peninsula Laboratories (Belmont, Calif.). Human ANP (99-126) was also used as the standard and label (Peninsula Laboratories). The interassay and intraassay variabilities were 8% and 4.5%, respectively.

Statistical analysis. All data are presented as the mean and standard error of the man. Paired or unpaired *t* tests (with Bonferroni correction for multiple comparisons) or one-way analysis of variance were used for statistical analysis. A p value <0.05 was considered significant except where the Bonferroni correction was used, in which case a p value <0.01 was significant.

This study had the approval of the institution's Human Subjects Committee and it was determined that consent forms were not necessary for the collection of umbilical cord blood.

Results

Table I shows the plasma ANP levels obtained in paired umbilical arterial and venous samples collected at the time of delivery. The levels in the umbilical artery were significantly higher than those in the umbilical vein ($p < 0.001$). Table I also shows the ANP levels in paired umbilical arterial samples. The ANP levels present in the umbilical artery at the time of delivery were almost 100% greater than those in the artery 10 minutes later ($p < 0.001$). The bottom of Table I shows the ANP levels in paired umbilical venous specimens. Again the levels in the umbilical vein at the time of delivery were greater than those 10 minutes later ($p < 0.001$).

Fig. 1 shows the ANP incubation studies done to determine if a peptidase that can degrade ANP is present in the umbilical circulation. The recovery of added ANP was 94% at 4° C and did not change when the plasma was incubated at 37° C for up to 30 minutes.

Fig. 2 shows the plasma ANP levels obtained in the umbilical artery at the time of delivery in the different patient groups studied. The average level in the normal population that underwent vaginal delivery at term was 51 ± 11 pg/ml. This level was not significantly different from the ANP levels obtained in the group delivered by cesarean section without labor or the group with prolonged pregnancies uncomplicated by fetal distress. The groups with preeclampsia and fetal distress both had significantly higher ANP levels (147 ± 41 and 334 ± 140 pg/ml, respectively) than the normal population at term ($p < 0.01$).

Comment

In this study we have attempted to identify some of the factors that may be involved in human fetal ANP metabolism and secretion. Our finding that umbilical arterial ANP levels are significantly greater than venous levels is in agreement with an earlier report by Yamaji et al.[13] and suggests that the placenta may be involved in the degradation or clearance of ANP. This is supported by a recent study that identified ANP receptors on the fetal side of the placenta.[12] Other investigators have failed to find any umbilical arterial-venous difference in ANP levels.[14] This could be related to the time interval from delivery to sampling of the umbilical vessels. In our study the average arterial-venous difference in ANP levels was 42 pg/ml when the samples were obtained at the time of delivery but was only 16 pg/ml when the samples were collected 10 minutes later.

The difference in ANP levels present in paired umbilical arterial (and paired umbilical venous) samples collected 10 minutes apart suggests that the umbilical vessels themselves are possible sites of ANP uptake or metabolism. This does not appear to be due to the presence of a circulating peptidase in the umbilical placental circulation because we did not observe any degradation of exogenous ANP in umbilical plasma after 30 minutes of incubation at 37° C. The umbilical vascular endothelium may contain receptors responsible for the uptake and clearance of ANP from the circulation. In adults, ANP receptors have been localized to the endothelium and smooth muscle of large and small vessels.[6]

Our results suggest that labor and route of delivery (vaginal vs. abdominal) have no significant effect on umbilical arterial ANP levels. Prolonged pregnancy (in the absence of fetal acidosis or maternal complications) also had no effect on ANP levels. However, both preeclampsia and fetal distress were associated with significantly higher ANP levels in the umbilical artery than were found in the normal control group. Although gestational age differences may account for the elevated ANP levels, we doubt this because ANP levels obtained at the time of cordocentesis have been shown to be unrelated to gestational age.[17] In addition, the present study shows that the gestational age difference between term and prolonged pregnancies is not associated with any changes in ANP levels.

There are several potential explanations for the elevated umbilical arterial ANP levels found in the group with preeclampsia. Doppler studies of the human umbilical placental circulation have shown an increase in umbilical vascular resistance in pregnancies complicated by preeclampsia.[18] The increased vascular resistance could stimulate ANP release from the heart through changes in myocardial work, a proposed determinant of ANP secretion.[4] The fetus may also be

relatively volume-depleted and the functioning placental mass may be decreased. Thus a decrease in the volume of distribution and/or a decrease in the clearance of ANP from the circulation may be responsible for the elevated ANP levels. This study cannot distinguish between these possibilities.

Umbilical arterial ANP levels were also elevated in the group with fetal distress. Because of our relatively small numbers we did not attempt to analyze our results with respect to the cause of the fetal distress. However, all subjects had in common an umbilical arterial pH (or scalp sample) of ≤7.20. Fetal acidosis has been reported to be associated with elevations in fetal plasma norepinephrine, epinephrine, and arginine vasopressin levels.[19, 20] Perfusion of the isolated rat heart with epinephrine has been shown to stimulate ANP secretion, an effect that appears to be mediated by both α- and β-adrenergic receptors.[2] Arginine vasopressin has been shown to stimulate ANP release in vivo presumably as a result of secondary hemodynamic changes.[3] Hypoxia can also stimulate ANP secretion by as yet poorly understood factors.[10] In the fetus hypoxia and acidosis may be accompanied by hypertension, which could stimulate ANP release through alterations in myocardial work. As noted for the group with preeclampsia, alterations in clearance or volume of distribution may also be partially responsible for the high ANP levels.

The physiologic significance of the high ANP levels present in the umbilical circulation of patients with preeclampsia or fetal distress requires further investigation. However, we postulate that ANP may be one factor by which the fetus attempts to regulate blood flow.

Impact of antenatal dexamethasone administration on respiratory distress syndrome in surfactant-treated infants

Elaine E. Farrell, MD, Richard K. Silver, MD, Lois V. Kimberlin, RN, Eileen S. Wolf, RN, and Joanne M. Dusik, RN

Evanston, Illinois

Neonatal lung disease is primarily responsible for the perinatal morbidity and mortality associated with preterm birth. Recently exogenous surfactant replacement therapy has been used to prevent or treat respiratory distress syndrome. As part of a multicenter, preventive trial between February 1986 and December 1988 using calf-lung surfactant extract, we treated 147 infants with single dose calf-lung surfactant extract. We analyzed this experience to evaluate the possibility that antenatal steroids may be additive (with calf-lung surfactant extract) in reducing both the incidence and severity of respiratory distress syndrome. Although a reduction in the incidence of respiratory distress syndrome was observed among the 33 neonates exposed to antenatal dexamethasone when compared with the 114 infants given calf-lung surfactant extract alone, the difference was not significant (37.7% vs. 24.2% $p = 0.15$). However, comparison of neonatal subsets previously shown to benefit most from steroid use revealed an additive effect between calf-lung surfactant extract and dexamethasone in reducing both the incidence and severity of respiratory distress syndrome. Of the 99 singleton pregnancies, only 2 of 16 infants treated with calf-lung surfactant extract and dexamethasone developed respiratory distress syndrome, compared with the 33 of 83 calf-lung surfactant extract cases ($p < 0.05$). A similar reduction was observed in infants between 28 and 32 weeks' gestation (calf-lung surfactant extract, 21 of 79 vs. calf-lung surfactant extract and dexamethasone, 0 of 24; $p < 0.05$). A reduction in disease severity was observed in male offspring (moderate or severe respiratory distress syndrome only; 22 of 63 vs. 2 of 22; $p < 0.05$). Potential confounding variables (e.g., gestational age at birth, birth weight, exposure to tocolytics before delivery, fetal pH at birth) were similar in all comparisons. We conclude that an additive effect between dexamethasone and calf-lung surfactant extract is observed in selected cases. It may therefore be appropriate to maximize antenatal steroid use in centers where exogenous surfactant is available. (AM J OBSTET GYNECOL 1989;161:628-33.)

Key words: Dexamethasone, respiratory distress, surfactant

Neonatal lung disease is primarily responsible for the perinatal morbidity and mortality associated with preterm birth. Until recently, specific therapy aimed at reducing the incidence of respiratory distress syndrome (RDS) has been limited to antenatal management strategies. These have included preterm labor prevention through risk assessment, early diagnosis, and aggressive use of tocolytic therapy and selected administration of antenatal steroids. The efficacy of steroid therapy in reducing the incidence of RDS has been confirmed in many studies,[1-3] including the national collaborative trial.[4] However, maternal steroid therapy is generally underutilized because of many factors, including the unanticipated nature of preterm delivery, the inability to delay delivery until steroid therapy can be completed, and the limited obstetric endorsement of this approach. In contrast, postnatal therapy with exogenous surfactant has shown great promise as both a prophylactic measure (to prevent RDS in neonates at risk) and a specific therapy (given after the diagnosis of RDS is made). Randomized preventative trials have demonstrated a significant reduction in the incidence of RDS with both bovine and human preparations of surfactant.[5-7] Improved outcome has also been reported in prospective trials designed to treat neonates with established RDS.[8, 9]

At first glance the encouraging results with surfactant replacement therapy, combined with the ability to prospectively identify and treat all neonates at risk, would favor surfactant treatment over antenatal steroid administration. However, in one report neonates exposed to both maternal steroid therapy and postnatal surfactant replacement had the lowest incidence of RDS when compared with patients receiving either treatment alone.[10] A synergistic response has also been identified in preterm animal models.[11, 12] As part of a multicenter,

preventive trial with calf-lung surfactant extract,[13] we have treated infants born between 24 and 32 weeks' gestation with calf-lung surfactant extract. In this report we analyze our own experience to evaluate the possibility that antenatal steroids may be additive (with calf-lung surfactant extract) in reducing both the incidence and severity of RDS.

Material and methods

Study population. Between February 1986 and December 1988 calf-lung surfactant extract was administered to 147 neonates delivered from 121 patients, between 24 and 32 weeks of gestation. Obstetric complications included advanced preterm labor, single-agent tocolytic failure, bleeding placenta previa, and maternal conditions that warranted preterm delivery. Multiple births complicated 22 pregnancies (twins = 19, triplets = 1, quadruplets = 2) and accounted for 48 neonates (1 twin-acardiac pair). A total of 45 neonates were exposed to antenatal steroid therapy, but only 33 completed therapy before delivery. These infants were compared with the remaining 114 neonates treated with calf-lung surfactant extract alone.

Steroid administration. Steroid therapy was administered at the discretion of the managing obstetrician. The decision to treat was independent of consent for the calf-lung surfactant extract trial. Dexamethasone (5 mg) was given intramuscularly every 12 hours for a total of four doses. Repeat administration was accomplished every 7 days until either delivery or 32 weeks' gestation. A mature phospholipid profile (lecithin/sphingomyelin ratio $\geq 3:1$) precluded both steroid therapy and calf-lung surfactant extract administration.

Calf-lung surfactant extract. Calf-lung surfactant extract is derived from saline lavage of fresh calf lungs; its physical and chemical properties are similar to endogenous surfactant.[7] The infants in this study were enrolled as part of a phase III, uncontrolled, open trial sponsored by the Department of Pediatrics at Buffalo Children's Hospital. Administration of calf-lung surfactant extract followed an established protocol.[7] Immediately after delivery and before assisted ventilation, the neonatology staff intubated each infant and introduced calf-lung surfactant extract through a specially adapted endotracheal tube. The dose of calf-lung surfactant extract was chosen based on gestational age and estimated fetal weight by ultrasonography. For gestational ages <29 weeks or weights <1200 gm, 3 ml (105 mg) of calf-lung surfactant extract was administered. A dose of 210 mg was used in the remaining infants. After instillation, ventilation was established and the infant was stabilized and transferred to the special care nursery. Further treatments were provided in a routine fashion with the exception that endotracheal suctioning was withheld for the first 2 hours after calf-lung surfactant extract instillation.

Definition of RDS. The diagnosis of RDS was made in those neonates who demonstrated (1) an oxygen requirement beyond 24 hours of life, (2) serial chest roentgenographic findings (reticulogranular pattern), and (3) a clinical course and ventilatory parameters compatible with the diagnosis. Respiratory distress syndrome was defined as mild if the FiO_2 remained <0.40 and the mean airway pressure was <8 mm H_2O. FiO_2 and mean airway pressure values of 0.40 to 0.69 and 8 to 11, respectively, defined moderate RDS, whereas neonates with FiO_2 >0.70 and mean airway pressure >12 were considered to have severe disease.

Data analysis. Maternal records were reviewed and both demographic and obstetric variables were coded. Neonatal data were obtained including categoric variables (e.g., the incidence and severity of RDS, intraventricular hemorrhage, pneumothorax and pulmonary interstitial emphysema, necrotizing enterocolitis and bronchopulmonary dysplasia), and continuous measures (e.g., specific ventilator parameters). Comparison between the two groups was accomplished with χ^2 analysis for discrete data and unpaired, two-tailed t tests for continuous variables. Significance was considered at $p < 0.05$.

Results

Comparison of maternal demographics and indications for delivery were similar in both the calf-lung surfactant extract only and calf-lung surfactant extract plus dexamethasone groups. Mean gestational age was the same in each group (29.3 weeks), and mean birth weights were also similar (calf-lung surfactant extract, 1340 gm vs. calf-lung surfactant extract plus dexa-

methasone, 1231 gm). Table I outlines other perinatal variables in this comparison. A greater proportion of multiple births was observed in the calf-lung surfactant extract plus dexamethasone group (17/33 vs. 29 of 114; $p < 0.01$), which accounted for part of the difference seen in the rate of cesarean delivery. Exposure to tocolytic therapy was equivalent in both groups, and no differences were identified in fetal acid-base status at birth (as measured by arterial cord pH or the proportion of acidemic values with pH <7.20).

Comparison of neonatal outcome is shown in Table II. Although a trend favoring neonates treated with calf-lung surfactant extract plus dexamethasone with regard to RDS and intraventricular hemorrhage was noted, the outcomes were similar. Because of the disparity in multiple births, we performed the same comparisons, restricting analysis to singleton pregnancies only. Table III summarizes these observations. A significant reduction in the incidence of RDS was observed; no infant had moderate or severe disease in the calf-lung surfactant extract plus dexamethasone group. Although no statistical differences in mortality were encountered, 11 of the 12 respiratory deaths occurred in the calf-lung surfactant extract group. In addition, 16 of 17 intraventricular hemorrhages were found in those neonates who received calf-lung surfactant extract only. The fetal acid-base status, male/female ratio, gestational age at delivery, and birth weights were all similar in this comparison.

Because the benefit of antenatal steroid therapy is less certain before 28 weeks' gestation, we also analyzed the data after excluding those infants delivered between 24 and 27 weeks of pregnancy (Table IV). A reduction in the incidence and severity of RDS was again observed in this calf-lung surfactant extract plus

dexamethasone cohort. This reduction occurred despite a trend toward lower birth weight and lesser gestational age in the calf-lung surfactant extract plus dexamethasone group ($p < 0.1$ for both comparisons). The diagnosis of small for gestational age (<10th percentile birth weight) did not confound this comparison (calf-lung surfactant extract, $n = 4$; calf-lung surfactant extract plus dexamethasone, $n = 3$), and no differences in either the percentage of multiple births or in the male/female ratio were seen.

Since the benefit of antenatal steroid therapy is presumedly greatest in female and nonwhite infants,[4] analyses were also accomplished with gender and race as independent variables. As shown in Table V, female neonates experienced more favorable outcomes with regard to both respiratory disease and survival. These differences could not be attributed to more frequent steroid treatment in the female group. In fact, 22 (26%) of the males were exposed to dexamethasone compared with only 11 (18%) females. To determine if an inadequate response to antenatal steroids (by the male fetus) was responsible for the better female outcome, we analyzed the males separately (comparing steroid treated and untreated subsets, Table VI). A significant reduc-

tion in moderate or severe RDS was observed in the calf-lung surfactant extract plus dexamethasone male cohort despite a disproportionate number of multiple births in that same group (55% vs. 14%; $p < 0.001$). An overall reduction in the incidence of RDS was also observed in the nonwhite neonates when compared with white infants (21% vs. 41%; $p < 0.05$) despite similar exposure to antenatal dexamethasone.

Comment

In this study we observed a consistent reduction in both the incidence and severity of RDS in selected neonates receiving calf-lung surfactant extract after exposure to antenatal dexamethasone. The fact that steroid administration was at the discretion of the managing physician may have introduced selection bias. However, potential confounding variables, as compared between the steroid-treated and untreated groups, were similar. The absence of a steroid-only cohort was not intentional. Since the introduction of the calf-lung surfactant extract trial at our institution, nearly uniform consent has been obtained so that all eligible infants have received the surfactant preparation. Therefore any neonate exposed to steroids would eventually receive calf-lung surfactant extract if delivered before 33 weeks' gestation. The study by Kwong et al.[10] had a steroid-only group for comparison because in that study steroid exposure constituted an exclusion criteria to calf-lung surfactant extract administration. They observed a synergism between betamethasone and calf-lung surfactant extract, but only a small number of infants were studied and the gestational age range (24 to 27 weeks' gestation) was limited. In contrast, the additive effect seen in our study was found among singleton pregnancies and occurred during the gestational age interval traditionally associated with successful induction of phospholipid synthesis.[4]

Our own analysis of very premature neonates (24 to 27 weeks) was hindered by the size of this particular cohort and its composition. Of the 45 infants <28 weeks' gestation at birth, only nine were exposed to antenatal steroids; seven of these were products of multiple gestations. A larger experience with more singleton pregnancies, or a randomized prospective trial of dexamethasone in very premature, calf-lung surfactant extract–treated neonates, might confirm the apparent synergism reported in the study by Kwong et al.[10]

The impact of gender on outcome was generally consistent with prior observations concerning steroid use. In animal models the "male disadvantage" has been attributed to delayed maturation of type II pneumocytes secondary to circulating testosterone.[11] In the collaborative trial,[4] steroid-exposed females experienced a significant reduction in RDS when compared with placebo controls (4.8% vs. 18.8%), whereas male neonates showed no apparent response (14.9% vs. 14.1%).

†$p < 0.05$.

Female infants also faired better in our study, but this may have been independent of steroid use, since no difference in the incidence of RDS was noted between the females treated with calf-lung surfactant extract plus dexamethasone or calf-lung surfactant extract (18% vs. 23%, respectively). In contrast the male infants demonstrated an additive response, with less respiratory distress syndrome in the calf-lung surfactant extract plus dexamethasone subset (49.2% vs. 27.3%; $p < 0.05$).

It is notable that the mean gestational age in our comparison (29 weeks) is significantly younger than that reported in collaborative trial (31 weeks), and the corresponding prevalence of RDS in our male infants (44%) differs from that of the collaborative trial (14%). Thus an impact of steroid treatment on the incidence of RDS may have been more readily identified in our study population.

It is tempting to speculate that the additive effect observed between steroids and calf-lung surfactant extract is directly related to increased phospholipid synthesis after enzymatic induction by dexamethasone. The addition of topical surfactant in the presence of enhanced, endogenous phospholipid production would increase the total surfactant content available to the neonatal lung. Our observation of clinical improvement associated with calf-lung surfactant extract plus dexamethasone in the same subsets of neonates traditionally thought to benefit from enhanced endogenous production supports this theory. In conflict with this interpretation are the reports of Ikegami et al.[11, 15] They observed an increase in preterm lung compliance in steroid- and surfactant-treated rabbit lungs but were unable to demonstrate a quantitative difference in alveolar surfactant pool sizes between steroid-exposed and unexposed groups. They suggested that antenatal steroids may impact on respiratory function by inducing structural modifications (e.g., maturation of the alveolar-capillary barrier providing for decreased protein leakage into the alveolar space) that prevent or limit lung injury. A study by Fiascone et al.[12] also supports the concept of a "nonsurfactant" effect of corticosteroids resulting in enhanced pulmonary compliance.

In summary, an additive effect between dexamethasone and calf-lung surfactant extract has been observed. We identified a decrease in both incidence and severity of RDS in those neonates exposed to steroid therapy and single-dose, prophylactic exogenous surfactant. Specific groups of neonates experiencing benefit included singleton infants, male infants, and those infants born between 28 and 32 weeks of gestation. It may therefore be appropriate to maximize antenatal steroid use in centers where exogenous surfactant is available. A prospective, randomized evaluation comparing calf-lung surfactant extract with calf-lung surfactant extract plus dexamethasone should be undertaken to confirm these observations.

Cocaine abuse during pregnancy: Peripartum prevalence and perinatal outcome

Mark G. Neerhof, DO, Scott N. MacGregor, DO, Sandy S. Retzky, DO, and Terence P. Sullivan, DO

Chicago, Illinois

The frequency of cocaine abuse during pregnancy has increased markedly in recent years. Cocaine abuse during pregnancy has been associated with significant perinatal morbidity and mortality. In this study a large population of pregnant women were tested for drug use at the time of their admission to the hospital for labor and delivery. During the study period a total of 138 (8%) of 1776 patients who were delivered of infants had positive urine toxicologic screening tests for cocaine. Moreover, the prevalence of peripartum cocaine abuse increased considerably during the study period. The perinatal outcomes of the 138 patients whose urine samples yielded positive test results for cocaine were compared with those of the 88 control patients with negative results. Cocaine use was associated with lower gestational age at delivery and higher incidences of preterm delivery, premature rupture of the membranes, and small-for-gestational-age infants. When compared with control infants, infants of mothers who used cocaine had more instances of neonatal morbidity and longer hospitalizations. In this study peripartum cocaine abuse was common, increased during the study period, and was associated with perinatal morbidity. (Am J Obstet Gynecol 1989;161:633-8.)

Key words: Cocaine abuse, prevalence, perinatal morbidity

The frequency of cocaine abuse has increased markedly in the United States during the last decade.[1] Among the reasons contributing to the epidemic abuse of this substance are the following: widespread availability, the seductive euphoria associated with its use, and the possibility of using this agent without intravenous injection. The increased abuse of cocaine has also led to the recognition of the potentially catastrophic complications.[2, 3] Reports of cocaine abuse in pregnancy have focused attention on the effects of cocaine on the fetus and newborn.[4-13] However, few data examining the prevalence of cocaine abuse among pregnant women have been published.[14] In this report we evaluated the prevalence of cocaine abuse among a large population of pregnant patients immediately before delivery and the perinatal outcome in these patients.

Table I. Maternal characteristics

Characteristic	*Cocaine-positive group (mean ± SD) (n = 138)*	*Control group (mean ± SD) (n = 88)*	*Significance*
Maternal age (yr)	25.8 ± 4.7	23.9 ± 5.8	$p < 0.005$
Gravidity	3.8 ± 2.0	2.7 ± 1.6	$p < 0.0001$
Parity	2.2 ± 1.7	1.2 ± 1.2	$p < 0.0001$
Maternal hospitalization (days)	3.0 ± 1.9	2.7 ± 1.2	NS

admitted to the Labor and Delivery Unit underwent a urine toxicologic screening. This policy was instituted for the following reasons: (1) Cocaine abuse has been recognized with greater frequency among our obstetric population; (2) increased perinatal morbidity and mortality associated with cocaine abuse in pregnancy has been described[4-13]; (3) it was deemed important to identify both mothers in need of treatment for chemical dependency and infants in need of long-term neurodevelopmental follow-up. Urine toxicologic screening was performed with the Syva Emit urine toxicology assay kit (Syva Company, Palo Alto, Calif.). Substances screened included cocaine, opiates, methadone, amphetamines, barbiturates, benzodiazepines, and propoxyphene. Thorough drug histories and informed consents were obtained before urine toxicologic screening.

From September 1, 1986, to August 31, 1988, 1776 consecutive women delivered of their infants at our institution had urine toxicologic screening at the time of admission to the Labor and Delivery Unit. Those women with positive test results for cocaine composed the study population. A control group (n = 88) was selected from the general obstetric population for purposes of comparison. The controls were selected as follows: Every twentieth delivery during the study period was considered as a control candidate; those denying a history of cocaine abuse and having negative test results for cocaine were included in the control group; those with positive test results for cocaine were excluded, and the next woman delivered in succession who denied cocaine abuse and had negative test results for cocaine was considered as a control.

Multiple substance abuse was frequently observed among the study group. Those with positive screening results for cocaine alone (group 1) were compared with those who had positive screening results for cocaine plus additional illicit substances (group 2) in an attempt to delineate further the effects of multiple substance abuse on perinatal outcome.

Continuous data of the study and control groups were compared with the appropriate t test, and discrete data were compared by means of either χ^2 or Fisher's exact tests. Numerous obstetric and neonatal complications were examined; therefore pairwise comparisons with χ^2 or Fisher's exact tests were considered statistically significant for these parameters at $p < 0.01$ (based on Bonferroni's correction[15]).

Results

One hundred thirty-eight (8%) of 1776 women had positive test results for cocaine. The incidence of cocaine-positive urine toxicologic screens increased steadily during the study period (Fig. 1). Fourteen (4%) of 397 patients who were delivered of their infants during the first 6 months of the study had positive test results for cocaine. In contrast, during the last 6 months, 60 (12%) of 514 had positive screens for cocaine. Drug history alone was successful in identifying only 59 (43%) of the 138 women who had positive test results for cocaine. All patients who initially denied cocaine use but had positive urine toxicologic screens subsequently admitted to using cocaine after being confronted with the test results. Neonatal urine toxicologic screening was performed on 114 of the 140 infants whose mothers screened positive for cocaine, and 83 (73%) of these had positive screens for cocaine.

Maternal characteristics of the study and control groups are compared in Table I. Maternal age, gravidity, and parity were significantly higher in the study population than in the control group. Racial distribution and medical complications were similar in both groups.

Obstetric data of the two groups are summarized in Table II. The incidences of preterm delivery, premature rupture of the membranes, and small-for-gestational-age infants were significantly greater in the study group than in the control group. The frequencies of abruptio placentae and low Apgar scores (defined as ≤3) were greater in the study group than in the control group; however, these differences were not statistically significant.

Neonatal data are summarized in Table III. Among the study neonates, 41 (29%) displayed clinical evidence of withdrawal, including tremulousness, irritability, poor feeding, and diarrhea. Apnea and/or abnormal pneumograms were present in 20 (14%) study infants. Congenital anomalies were more common in the study infants and included ventricular septal defect ($n = 2$), atrial septal defect ($n = 1$), complete heart block ($n = 1$), inguinal hernia ($n = 2$), esophageal atresia ($n = 1$), hypospadias ($n = 1$), cleft lip and palate with trisomy 13 ($n = 1$), and polydactyly ($n = 1$). The perinatal mortality rate was higher in the study group than in the control group (50 vs. 0 per 1000, respectively). Intrauterine fetal death occurred in three study pregnancies and neonatal death occurred in four. The incidence of prolonged hospitalization was also significantly greater in the study group than in the control group.

Multiple substance abuse was frequently observed among the study group. Twenty-four of 138 (17%) study patients had positive urine toxicologic screens for illicit substances in addition to cocaine. Sixteen patients had positive results for one additional substance (15 for opiates and one for methadone), whereas eight were positive for two additional substances.

Comparisons of patients with positive screens for cocaine alone (group 1, $n = 114$) versus those with pos-

> 10 Days	35 (31%)	13 (54%)	$p < 0.01$

*Group 1 includes two twin gestations ($n = 116$).

†Birth weight < 10th percentile by birth weight curves of Brenner et al.[16]

‡Group 1 includes two twin gestations and excludes three gestations complicated by intrauterine fetal death ($n = 113$).

itive screens for cocaine plus additional illicit substances (group 2, $n = 24$) are summarized in Table IV. Maternal age, gravidity, and parity were similar in both groups. In addition, obstetric data, including gestational age at delivery, infant birth weight, and frequencies of preterm labor and small-for-gestational-age infants, were similar in groups 1 and 2. Compared with infants of mothers abusing cocaine alone, infants of mothers abusing cocaine plus additional substances had significantly higher incidences of neonatal withdrawal, congenital anomalies, and prolonged hospitalization (>10 days).

Comment

The prevalence of cocaine abuse among the general population in the United States has increased dramatically during the past decade.[1] However, few data exist documenting the prevalence of cocaine abuse among pregnant women.[14] Our data suggest that peripartum cocaine abuse was common and increased dramatically during the study period among pregnant women delivered at our institution. The rising incidence of positive urine toxicologic screens appears to reflect an increasing prevalence of cocaine abuse among our obstetric population. There was no change in the testing methods during the study period, nor was there any appreciable change in the demographic characteristics of our obstetric population. Furthermore, our data very likely underestimate the actual prevalence of cocaine abuse in pregnancy. Cocaine metabolites are usually present in the urine for only 72 hours after ingestion; this study design, at best, only identified women abus-

ing cocaine within 72 hours before admission to the hospital. Those patients with positive test results for cocaine at the time of admission may represent only a fraction of those abusing cocaine at some time during pregnancy.

Previous reports have suggested that cocaine abuse in pregnancy may be associated with adverse perinatal outcome.[4-13] The perinatal morbidity that has been associated with cocaine abuse includes lower infant birth weight, lower mean gestational age at delivery, increased incidence of preterm delivery, and delivery of small-for-gestational-age infants. In addition, increased frequencies of abruptio placentae, congenital anomalies, and neonatal withdrawal have been observed. Our data support many of these findings. When compared with the control group, those women with positive test results for cocaine had lower gestational ages at delivery and lower infant birth weights, as well as higher incidences of preterm delivery, premature rupture of the membranes, and small-for-gestational-age infants. We also found that infants born to cocaine-abusing mothers had neonatal complications, including withdrawal and apnea or abnormal pneumograms, more frequently than control infants. In addition, the perinatal mortality rate in the cocaine-positive group was clinically alarming.

Several factors may have influenced our study results. First, neither the quantity of cocaine nor the pattern of abuse throughout pregnancy was available. An accurate estimation of the amount of cocaine used is problematic. We chose not to rely on patient recall for this information, since our data suggested that drug histories were not reliable among our patients. Our study identified only those women abusing cocaine immediately before delivery. Chasnoff et al.[13] have suggested that cocaine abuse during the third trimester may be associated with increased perinatal morbidity when compared with cocaine abuse limited to the first and second trimesters. Second, women abusing cocaine are likely to have abused multiple substances during their pregnancies, further confounding attempts to establish a cause-and-effect relationship, rather than an association, between a particular illicit substance and adverse perinatal outcome. In an effort to further delineate the impact of multiple substance abuse on perinatal outcome, cocaine-positive study patients were divided into two groups, those with positive screens for cocaine alone (group 1) and those with positive screens for cocaine plus additional illicit substances (group 2). Obstetric complications of these two groups were similar (Table IV). Infants of multiple-substance abusers were more likely to undergo withdrawal and require prolonged hospitalization than infants whose mothers had positive screens for cocaine alone. Those women abusing cocaine and additional substances during pregnancy may be at greatest risk for adverse perinatal outcome; however, significant perinatal morbidity was observed in both groups. Third, cocaine and multiple-substance abusers tend to have poor nutritional habits and adverse socioeconomic situations and often obtain limited prenatal care. Such factors may further influence differences in perinatal outcome between the cocaine-abusing group and the control group.

The prevalence of cocaine abuse and the frequency of adverse perinatal outcome associated with its use in our study emphasize the need to identify women abusing illicit substances. Identification during pregnancy would fascilitate increased antenatal surveillance, psychiatric and social service referral for substance-abusing mothers, and long-term neurodevelopmental follow-up for infants exposed to cocaine in utero. To our knowledge only one report has been published to date evaluating the prevalence of cocaine abuse in an obstetric population. Little et al.[14] reviewed data of 102 obstetric patients and estimated that the prevalence of cocaine abuse in their obstetric population was 9.8% on the basis of drug history. Drug history alone may be inadequate in identifying substance abusers. Indeed, in our study only 59 of 138 women who had cocaine-positive urine toxicologic test results admitted substance abuse on initial evaluation. Urine toxicologic screening may be beneficial in identifying illicit substance abusers, especially in a large urban population such as ours, so that proper maternal, prenatal, and neonatal care can be offered.

In conclusion, cocaine abuse during pregnancy appears to be alarmingly prevalent among our obstetric population and has increased dramatically. Our data also suggest an association between cocaine abuse during pregnancy and adverse perinatal outcome. Thus it appears that cocaine has contributed significantly to perinatal morbidity and mortality in our obstetric population. Complications in cocaine-exposed neonates associated with prolonged hospitalization may contribute significantly to health care costs and the utilization of health care resources.

Do the current standards for glucose tolerance testing in pregnancy represent a valid conversion of O'Sullivan's original criteria?

David A. Sacks, MD,[a] Salim Abu-Fadil, MD,[a] Jeffrey S. Greenspoon, MD,[b] and Nick Fotheringham, PhD[c]

Bellflower and Los Angeles, California

The venous plasma values for the 100 gm glucose tolerance test endorsed by the Second International Workshop-Conference on Gestational Diabetes represent an arbitrary conversion from O'Sullivan's original values. The latter were calculated from whole blood by means of the Somogyi-Nelson method. The factor used to convert the whole blood values to plasma glucose values was empirically derived in a population in whom pregnancy status was not stated. A conversion factor derived from a nonpregnant population may systematically overestimate plasma glucose concentration when applied to a pregnant population. Paired specimens obtained from 995 consecutive pregnant patients were analyzed by the Somogyi-Nelson method on whole blood and the glucose oxidase method on plasma. A conversion formula was derived and was used to estimate plasma glucose values and 95% confidence limits equivalent to whole blood values. Application of this formula yields plasma glucose oxidase glucose tolerance test values of fasting, 96 mg/dl; 1 hour, 172 mg/dl; 2 hours, 152 mg/dl; and 3 hours, 131 mg/dl. These values are all lower than those currently endorsed. (Am J Obstet Gynecol 1989;161:638-41.)

Key words: Gestational diabetes, glucose tolerance

In 1964 O'Sullivan and Mahan[1] published a study establishing criteria for the oral glucose tolerance test (GTT) in pregnancy. Two or more values (fasting, 90 mg/dl; 1 hour, 165 mg/dl; 2 hour, 145 mg/dl; 3 hour, 125 mg/dl) had to be equaled or exceeded to diagnose gestational diabetes. The glucose concentrations were determined from whole blood by the Somogyi-Nelson assay, a chemical method. Enzyme methods for measuring glucose (e.g., glucose oxidase) are more specific and have largely replaced chemical methods.[2] Furthermore, because estimates of glucose concentration in whole blood may be affected by the hematocrit,[3] they have been replaced by plasma assays.

The plasma glucose values endorsed first by the Na-

tional Diabetes Data Group[4] and subsequently by the Second International Workshop-Conference on Gestational Diabetes Mellitus (fasting, 105 mg/dl; 1 hour, 190 mg/dl; 2 hour, 165 mg/dl; 3 hour, 145 mg/dl) represent an arbitrary conversion from O'Sullivan's original values.[5] Although the factor used to convert the original whole blood–Somogyi-Nelson values to plasma enzyme assay values is not explicitly stated, it closely approximates the 13% to 16% reported in other studies. Those studies were notable for not explicitly stating the subjects' pregnancy status.[6, 7] As Schwartz and Brenner[8] noted, a factor derived from a nonpregnant population used to convert whole blood glucose to plasma glucose may systematically overestimate the plasma glucose in pregnant subjects. The purpose of this study was to empirically derive a formula to convert glucose concentrations in whole blood measured by the Somogyi-Nelson method to glucose concentrations in plasma obtained by the glucose oxidase method for use during pregnancy.

Material and methods

Nine hundred ninety-five consecutive predominantly Hispanic patients having routine 50 gm 1-hour glucose screening tests during pregnancy were studied. The glucose screening test was performed according to the recommendations of the Second International Workshop-Conference on Gestational Diabetes.[5] A total of 14 ml of blood was obtained from each patient on one occasion and separated equally into two tubes, each containing 14 mg of potassium oxalate as an anticoagulant and 17.5 mg of sodium fluoride to inhibit glycolysis. The tube used for the plasma assay was spun at 1570 *g* for 10 minutes to separate the plasma. The supernatant was assayed by an automated glucose oxidase method (Trendar Auto-Pak; HiChem, Inc., Anaheim, Calif.). The Somogyi-Nelson assay of whole blood was done by a standard manual method.[9] All testing was performed by the same laboratory. No changes in the technology of glucose assays occurred during the course of this study. The interassay coefficient of variation for normal controls was 2.3% for the glucose oxidase and 1.5% for the Somogyi-Nelson method.

Multiple linear regression analysis was used to evaluate the relationship between glucose assays with the Somogyi-Nelson and glucose oxidase methods and the effect of hematocrit on this relationship. These analyses were performed with BMDP Programs 2R and 6D. Demographic information was summarized with BMDP Program 2D.[10] The level of significance was set at $p < 0.05$.

Results

Among the 995 patients, 386 (38.8%) were nulliparous. The mean (±SD) maternal age was 26.1 ± 5.7 years. Two patients were tested in the first trimester, 234 (23.5%) in the second trimester, and 759 (76.3%) in the third trimester. The mean (±SD) glucose concentration was 109.1 ± 25.7 mg/dl for the whole blood–Somogyi-Nelson assay and 115.1 ± 26.7 mg/dl for the glucose oxidase assay. The respective ranges of values were 50 to 229 mg/dl and 47 to 235 mg/dl.

The formula for the regression line with the whole blood–Somogyi-Nelson assay as the independent variable is P = 4.391 + 1.015 WB, where P is plasma–glucose oxidase and WB is whole blood–Somogyi-Nelson. The 95% confidence interval of the slope was 1.001 to 1.029; the 95% confidence interval of the intercept was 4.03 to 4.75. The correlation coefficient between techniques was 0.976 ($p < 0.001$). The line of best fit and 95% confidence intervals are illustrated in

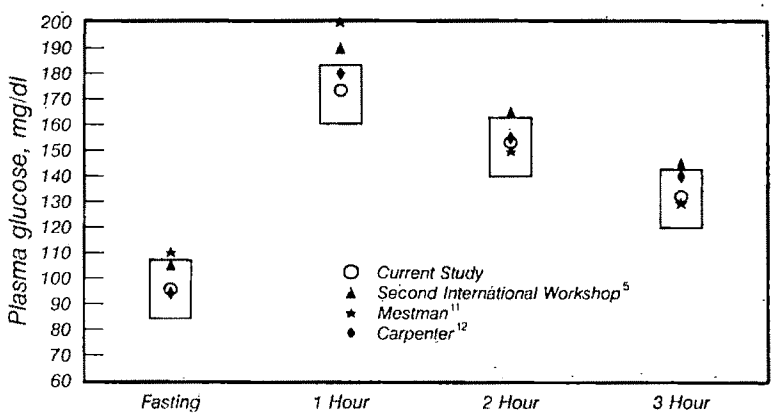

Fig. 2. Plot of criteria proposed by different references for glucose tolerance tests in pregnancy with 100 gm glucose load and glucose oxidase assay of plasma. Values in *boxes* represent 95% confidence intervals derived from data in this study for glucose oxidase assay of plasma, which would be equivalent to O'Sullivan's original GTT values.

Fig. 1. Application of the formula to O'Sullivan's whole blood–Somogyi-Nelson GTT values converts these to plasma glucose oxidase values of 96 mg/dl, 172 mg/dl, 152 mg/dl, and 131 mg/dl, respectively, for fasting, 1-hour, 2-hour, and 3-hour values. A comparison of these criteria with those published by others[5, 11, 12] with a 100 gm glucose load and a plasma–glucose oxidase assay is illustrated in Fig. 2. All values for the GTT proposed by Carpenter and Coustan[12] are within the 95% confidence intervals of the plasma–glucose oxidase equivalents derived from the current data.

Of the 995 patients studied, 572 had hematocrit samples drawn within 1 week of the glucose assays. Hematocrit values ranged from 26% to 43%. The slopes of the regression lines of P onto WB in the ranges 27.51% to 32.50%, 32.51% to 37.50%, and 37.51% to 42.50%, respectively, were not significantly different.

Comment

Several authors have used plasma–glucose oxidase values that they claimed were equivalent to the original Somogyi-Nelson–whole blood GTT criteria introduced by O'Sullivan and Mahan.[1] The conversion of these values requires consideration of both the laboratory method used and the blood component analyzed.

The initial step of the Somogyi-Nelson method is the preparation of a protein-free filtrate, which serves to remove nonglucose reducing substances found in red blood cells such as glutathione, glucuronic acid, ergothioneine, and ascorbic acid.[2] However, other hexoses (e.g., galactose, mannose) remain in the filtrate and may account for the higher "glucose" values reported for the Somogyi-Nelson method in comparison with enzyme methods.[2, 13] Technical factors within the Somogyi-Nelson assay also may alter test results. Mager and Farese[13] found significantly different results in the same specimens of whole blood by merely altering the sequence of the addition of reagents used in the preparation of the protein-free filtrate.

Because they confer maximum specificity of glucose estimations, enzyme methods (e.g., glucose oxidase and hexokinase) have largely replaced older chemical methods.[2] The hexokinase method is the current reference method, and the glucose oxidase method is the most commonly used glucose assay.[8] Glucose oxidase results correlate well with those obtained by the hexokinase assay.[2] Few studies have attempted to establish a quantitative relationship between Somogyi-Nelson and glucose oxidase assays. Mager and Farese[13] found that results obtained by Somogyi-Nelson assay were significantly higher (range, 2% to 6%) than those obtained by glucose oxidase when plasma was assayed. However, when these two methods were compared when whole blood was used, no consistent relationship was found.

Glucose assays of plasma offer significant advantages over those of whole blood. Interference from nonglucose reducing substances is minimized. Plasma more readily lends itself to automated assays than whole blood. Finally, and of critical relevance to pregnancy, whole blood assays for glucose may be influenced by hematocrit,[3] whereas plasma assays are not.

The concentration of glucose in plasma exceeds that in red blood cells. When the hematocrit is lower (the fewer the number of red cells per unit volume), the concentration of glucose in whole blood is higher and the difference between whole blood and plasma glucose values is lower.[3, 8] Because of the disproportionate expansion in plasma volume in relation to red blood cell mass during pregnancy,[14] pregnant patients may have lower hematocrit values than a nonpregnant population. Thus a factor used to convert whole blood to plasma glucose derived from a nonpregnant population may systematically overestimate plasma glucose

during pregnancy. O'Sullivan and Kantor[7] reported a mean difference of 13.4% between whole blood and plasma glucose when both were assayed by an automated ferricyanide method. Niejadlik et al.[6] found that plasma glucose values obtained by the hexokinase method exceeded by 13% the whole blood glucose values obtained by the Somogyi-Nelson method. In neither study was the subjects' pregnancy status noted.

As O'Sullivan and Kantor[7] reported, we were unable to detect a significant contribution by hematocrit to the differences in glucose values between assays. A potential explanation for this finding includes the narrow ranges of both observed hematocrit and glucose values. However, we did find a marked difference between our empirically derived conversion factor (approximately 5% to 6%) and those reported by others. It is of interest that the extrapolated values of Carpenter and Coustan,[12] which consider the effects of both method and blood component assayed, fall within the 95% confidence intervals of our empirically derived values (Fig. 2).

O'Sullivan's criteria for GTT in pregnancy are unique because they were both empirically derived and validated. Values that are 2 SDs above the mean of an unselected sample of 752 women were chosen because the proportion of patients meeting or exceeding these criteria approximated the prevalence of diabetes in the community (1.99%). In addition, when these criteria were applied to a second group of patients, it was found that those meeting criteria for gestational diabetes during pregnancy had a significantly higher incidence of diabetes 8 years after delivery than those who did not meet criteria for gestational diabetes.[1] Finally, O'Sullivan et al.[15] demonstrated significantly more perinatal losses among infants of women with gestational diabetes ≥25 years of age than among age-matched nondiabetic control women.

Unfortunately, both the Somogyi-Nelson laboratory method for glucose concentration and the blood component assayed (whole blood) in the 1964 study have more intrinsic variability than the enzyme assays of plasma in current use. Applying an arbitrary conversion factor to the original data may further detract from the accuracy of criteria proposed as equivalent. The ideal resolution of the issue would be to repeat O'Sullivan's study with an enzyme assay on plasma. Alternatively, critical examination of different proposed sets of GTT criteria relative to maternal, fetal, and neonatal outcome variables seems reasonable. It is our hope that the findings of this study will serve as a stimulus for further investigation.

How reliable is the fifty-gram, one-hour glucose screening test?

David A. Sacks, MD,[a] Salim Abu-Fadil, MD,[a] Jeffrey S. Greenspoon, MD,[b] and Nick Fotheringham, PhD[c]

Bellflower and Los Angeles, California

The Second International Workshop-Conference on Gestational Diabetes recommended screening all pregnant women with a 1-hour 50 gm oral glucose screening test, given without regard to time of day or time elapsed from the last meal. This study was designed to evaluate the reproducibility of that test, given under those clinical conditions. Thirty women with gestational diabetes and 80 control volunteers between 24 and 28 weeks' gestation were tested at the same time of day on two successive days. Of the 30 women with diabetes, three (10%) had glucose screening test results below the 135 mg/dl threshold on both days and 10 (33%) had results that straddled the threshold on successive days. Test results of 11 control women also straddled the threshold. Among these 21 women with results that straddled the threshold, there was no difference in mean glucose screening test results in diabetic women compared with nondiabetic ones. We conclude that, as currently recommended, the 1-hour glucose screening test is moderately reproducible. Reliance should not be placed on a single normal test result, particularly among patients with risk factors. (AM J OBSTET GYNECOL 1989;161:642-5.)

Key words: Gestational diabetes, screening for diabetes

The Second International Workshop-Conference on Gestational Diabetes recommended administering the 50 gm, 1-hour glucose screening test without regard to time of day or time elapsed from the last meal.[1] If the test administered under these clinical conditions is reproducible, then one may depend on a single glucose screening test result to reliably identify patients with gestational diabetes. However, if repetitive results of the same subject differ markedly, and especially if the test results straddle a threshold used to indicate that a glucose tolerance test (GTT) should be performed, then reliance on a single test may not be justified. The present study was designed to test the hypothesis that there is no significant difference in glucose screening test results obtained from the same subject on successive days.

Material and methods

Our protocol for screening for gestational diabetes has been previously reported.[2] Volunteers were recruited from two groups of predominantly Hispanic women. One group consisted of 84 obstetric patients who were not known to have glucose intolerance. These patients had a glucose screening test on two consecutive days between the twenty-fourth and twenty-eighth gestational weeks. Those whose test results equaled or exceeded 135 mg/dl on either or both days had a 3-hour GTT. Four of these 84 patients had gestational diabetes diagnosed by the GTT and are included with the gestational diabetic group for purposes of data analysis. The remaining 80 patients were termed controls.

The second group consisted of 26 women with gestational diabetes that was first diagnosed during the current pregnancy. These patients were identified by a glucose screening test result ≥135 mg/dl followed by a GTT that was diagnostic of gestational diabetes. After volunteering for the study, these 26 women had an additional glucose screening test on each of two consecutive days between the twenty-fourth and twenty-eighth gestational weeks. The GTT was not repeated in this group. None of the diabetic patients had initiated dietary and/or insulin therapy at the time the study was conducted.

On the first day of testing, the subjects were given a 1-hour, 50 gm glucose screening test, with a commercially prepared cola (Dolce-Hopping Bottling Co., Sunnyvale, Calif.). They were instructed to eat the same foods and engage in the same or similar physical activities at the same time of day on the following day and to return in exactly 24 hours for a second glucose screening test. The preparation for and conduct of both glucose screening and tolerance tests, as well as the criteria for defining diabetes, followed the recom-

mendations of the Second International Workshop-Conference on Gestational Diabetes.[1]

Gestational age was determined by clinical parameters including date of last menstrual period, early sizing, and sonographic examinations. Approval for this study was obtained from the Institutional Review Board of the Southern California Kaiser Permanente Research Program. A signed informed consent was obtained from each participant.

Plasma glucose assays were performed by an automated glucose oxidase method (Synchron CX3 System, Beckman Instruments, Brea, Calif.). Interassay coefficients of variation for normal controls (mean 90.6 mg/dl) and abnormal controls (mean 292.2 mg/dl), respectively, were 2.3% and 1.5%. Intraassay coefficients of variation for normal controls (mean 88.0 mg/dl) and abnormal controls (mean 294.4 mg/dl), respectively, were 1.8% and 1.0%.

Two-sample t tests and analysis of variance were used to compare mean glucose screening test values. Continuity-corrected χ^2 tests were used to compare frequencies of occurrence among patients. Product moment correlation coefficients and logistic regression analysis were used to evaluate relationships between variables. Descriptive statistics, t tests, χ^2 tests, correlation analysis, analysis of variance, and logistic regression were performed with BMDP Programs 2D, 3D, 4F, 8D, 2V, and LR.[3] Statistical results were considered significant at a level of $p < 0.05$.

Results

The mean ± SD for maternal age was 27.6 ± 6.4 years. Of the 110 patients, 43 (39%) were nulliparous. The mean ± SD for number of weeks' gestation on the first day of testing was 26.6 ± 1.4. The mean ± SD for time interval from first to second glucose screening test was 24 ± 2.6 hours.

The individual day-to-day glucose screening test results are displayed in Fig. 1. The mean day-to-day glucose screening test values for diabetic and control groups are shown in Table I. On both days, the mean value for the diabetic group was significantly greater than that of the control group. A two-way analysis of variance demonstrated no significant day-to-day differences in mean values for either diabetic or control group. The mean of the absolute day-to-day differences in values for women with diabetes approached but did not achieve a statistically significant difference from that of the control group (Table I).

Ten women with diabetes and 11 control women had glucose screening test values ≥135 mg/dl on only 1 day. Five of the values in the diabetic group equaled or exceeded the threshold on the first day of testing and five on the second day (Fig. 1). In contrast with the entire patient sample, there was no significant difference in mean glucose screening test results between these "straddler" diabetics and controls (Table I).

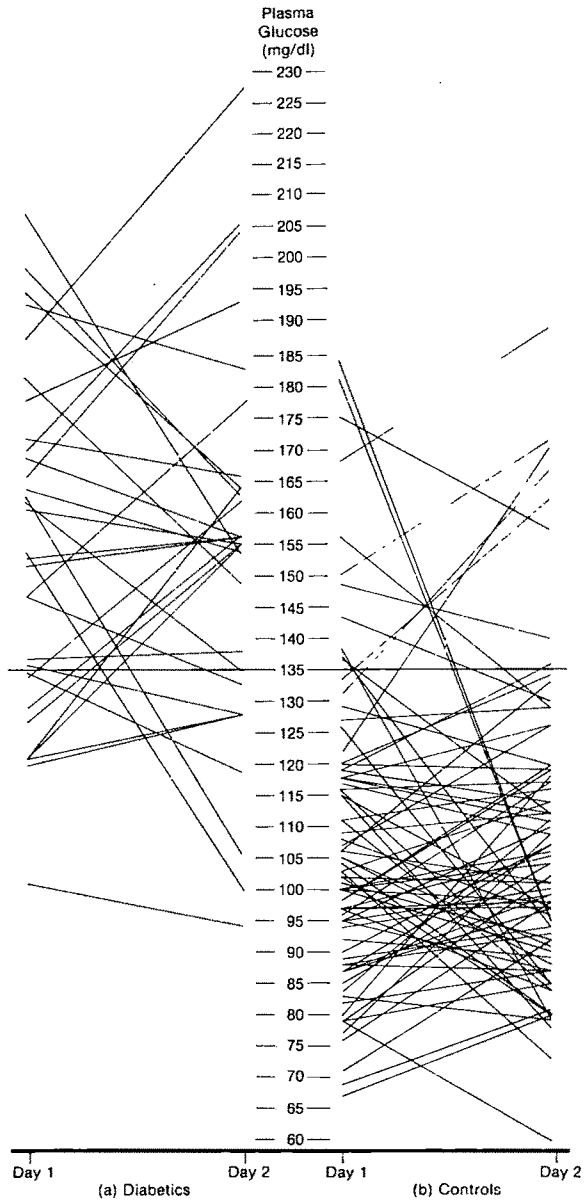

Fig. 1. Plot of glucose screening test results on day 1 and day 2 for gestational diabetic and control groups. A *line* connects values on successive days from the same individual. A threshold of 135 mg/dl was used to indicate that a GTT should be performed.

Fasting hyperglycemia was defined by a fasting plasma glucose level ≥105 mg/dl on the GTT. Among the 30 with gestational diabetes, fasting hyperglycemia occurred with approximately equal frequency in patients whose two glucose screening test results were below threshold (1 of 3, 33%), straddled the threshold (3 of 10, 30%), or exceeded the threshold (6 of 17, 35%).

The parameters investigated as independent risk fac-

Table I. Mean day-to-day differences in glucose screening test results

GST, Glucose screening test; *ΔGST*, day-to-day difference in GST values; *NS*, not significant. Straddlers are those patients whose test results equaled or exceeded the 135 mg/dl threshold on only 1 day.

tors were: family history of diabetes, obesity (defined as a prepregnancy weight ≥150 pounds), and age ≥25 years.[2] All of the 30 women with gestational diabetes had at least one risk factor. Seven of these 30 (23%) had only one risk factor, 11 (37%) had two, and 12 (40%) had all three. In contrast, significantly fewer (61 of 80 or 76%; $p < 0.05$) control women had one or more risk factors.

Comment

It is important to note that the selection of a 135 mg/dl threshold was somewhat arbitrary.[2,4] In general, the lower the threshold selected, the greater the sensitivity and the lower the specificity.[5]

This study was designed to be optimally consistent with the recommendations of the Second International Workshop-Conference on Gestational Diabetes.[1] Patients were therefore tested without regard to time of day or time elapsed from the last meal. Although there is objective evidence of patient compliance with temporal requirements (mean interval of 24 hours between glucose screening tests), compliance with instructions to maintain the same activity and diet on both days was not closely monitored. Coustan et al.[4] demonstrated that the ingestion of a mixed meal 1 hour before a glucose screening test significantly lowered test results in women with gestational diabetes in comparison with those tested after fasting. However, the absence of significant differences in 1-hour postglucose values relative to time after the last meal has been reported among nondiabetic pregnant[4] and nonpregnant[6] women. The degree to which diet, activity, and time interval from and content of the last meal may influence the reproducibility of the glucose screening test may be investigated by testing a patient sample in which these variables are more rigorously controlled (e.g., hospitalized patients).

A number of other studies have indicated that, despite rigid control of diet and activity, consecutive glucose challenge test results are poorly reproducible. Sisk et al.[7] noted a correlation coefficient of 0.66 in successive values 15 days apart in 96 male prisoners tested 1 hour after a 50 gm glucose load. Ackland et al.[8] reported significant day-to-day differences among seven male laboratory personnel undergoing a 50 gm glucose tolerance test on three successive days. Among 31 male prisoners who met criteria for diabetes, McDonald et al.[9] found that none did so on all six glucose tolerance tests administered over a year's time. However, Owens et al.,[10] reporting on four normal men who received 50 gm glucose challenges every 3 to 4 hours on 2 days of testing during two successive weeks, found no significant differences at most fixed time intervals after each challenge.

The positive correlation between magnitude of mean plasma glucose values and day-to-day variability also has been previously reported. Various authors[9, 11, 12] have noted both peak absolute value and maximal test-to-test differences 1 hour after the glucose challenge. In addition, Harding et al.[13] found a positive correlation between the area under the glucose tolerance curve and between-test variability.

The reasons for variability in results within the same subject from one test to another are not clear. In evaluating 52 women who had third-trimester GTTs during each of three pregnancies, O'Sullivan and Mahan[14] found that the majority of variation with repetitive testing was due to biologic variation within, more-so than between, individuals. Harding et al.[13] postulated that intrasubject differences in glucose concentrations are due to day-to-day fluctuations in glucose absorption and distribution, as well as hepatic glycolysis and gluconeogenesis.

The clinical consequences of this day-to-day variation in 1-hour postglucose screening in pregnancy are illustrated by the findings of the current study. Reliance on a single glucose screening test value <135 mg/dl would have resulted in missing eight of 30 (27%) cases of diabetes on any single given day (Fig. 1). Three of these cases of gestational diabetes would have been missed on both days. Had all cases of diabetes been ascertained from a group of women with known gestational diabetes, the latter number might have been larger. There did not appear to be a relationship be-

tween fasting hyperglycemia and whether the glucose screening test results were below, straddled, or met or exceeded the designated threshold. The relationship between fasting hyperglycemia in pregnancy and increased perinatal mortality has been previously noted.[15] Finally, it was not possible to distinguish glucose screening test results of "straddler" diabetics from those of "straddler" controls on the basis of day-to-day mean test values or mean differences in test results (Table I).

In conclusion, performing the 1-hour glucose screening test in pregnancy without regard to time of day or time elapsed from the last meal offers the advantages of simplicity and acceptability, and thus patient compliance. However, the data in this study suggest that a substantial proportion of cases of gestational diabetes may be missed by reliance on a single glucose screening test. From these data, it seems unlikely that a glucose screening test value ≤95 mg/dl would be associated with gestational diabetes. We therefore suggest that with values above this level reliance not be placed on a single "normal" test result, particularly among patients with identifiable risk factors.

Glycemic control in gestational diabetes mellitus—How tight is tight enough: Small for gestational age versus large for gestational age?

Oded Langer, MD, Judith Levy, MD, Lois Brustman, MD, Akolisa Anyaegbunam, MD, Ruth Merkatz, RN, and Michael Divon, MD

Bronx, New York

The relationship between optimal levels of glycemic control and perinatal outcome was assessed in a prospective study of 334 gestational diabetic women and 334 subjects matched for control of obesity, race, and parity. All women with gestational diabetes mellitus were instructed in the use of a memory-based reflectance meter. They were treated with the same metabolic goal according to a predetermined protocol. Three groups were identified on the basis of mean blood glucose level throughout pregnancy (low, ≤86 mg/dl; mid, 87 to 104 mg/dl; and high, ≥105 mg/dl). The low group had a significantly higher incidence of small-for-gestational-age infants (20%). In contrast, the incidence of large-for-gestational-age infants was 21-fold higher in the mean blood glucose category than in the low mean blood glucose category (24% vs. 1.4%, $p < 0.0001$). An overall incidence of 11% small-for-gestational-age and 12% large-for-gestational-age infants was calculated for the control group. A significantly higher incidence of small-for-gestational-age infants (20% vs. 11%, $p < 0.001$) was found between the control and the low category. In the high mean blood glucose category an approximate twofold increase was found in the incidence of large-for-gestational-age infants when compared with the control group ($p < 0.03$). No significant difference was found between the control and mean blood glucose categories (87 to 104 mg/dl). Our data suggest that a relationship exists between level of glycemic control and neonatal weight. This information is helpful in targeting the level of glycemic control while optimizing pregnancy outcome in gestational diabetes comparable to the general population. (Am J Obstet Gynecol 1989;161:646-53.)

Key words: Gestational diabetes, level of control, intrauterine growth retardation, macrosomia

In recent years tight glycemic control became a standard of care in the management of the pregnant diabetic in order to reduce perinatal mortality and morbidity. This resulted in the reduction of perinatal mortality to rates comparable to those observed in the normal population.[1,2] In contrast, the incidence of perinatal morbidity as reflected by metabolic disorders and macrosomia remains relatively high.[3,4] Perinatal mortality was prevented by recognition of the need for stringent metabolic control in the pregnant diabetic. However, paucity of information is available regarding the optimal level of glycemia that should be targeted to reduce perinatal morbidity.

Tight glycemic control may result in acute and chronic nutritional deprivation, which are linked to retarded fetal growth and substrate limitations. Fetal insulin levels are responsive to changes in substrate availability in either direction. The fetus grows to the limits allowed by the supply of critical nutrients. It can be anticipated that there will be a significant difference in neontal size in relation to the level of glycemic control in the mother.

In the early 1970s, Pedersen[5] recognized that maternal hyperglycemia is a cause for fetal hyperinsulinemia, leading to excess fetal growth. In contrast, we and other researchers have shown that relative maternal hypoglycemia is associated with intrauterine growth retardation (IUGR).[6,7] In this study we sought to answer the research question: What are the optimal levels of glycemic control that will maximize perinatal outcome? To resolve this issue, we investigated the association between different levels of glycemic control and neonatal weight size (large-for-gestational-age (LGA) vs. small-for-gestational-age (SGA) infants). We also evaluated the relationship between neonatal weight and selected maternal characteristics (e.g., obesity, treatment modality).

taken from 1985 to 1988. Women were matched for obesity, race, parity, and gestational age at delivery. Gestational diabetes mellitus was diagnosed in accordance with the National Diabetes Data Group Criteria and normal individuals by a normal oral glucose tolerance test (all values normal) during the third trimester.[8]

To promote optimal metabolic control, the gestational diabetic participants were instructed in the use of a memory-based reflectance meter to assure accurate and reliable collection of blood glucose data.[9] They were requested to test their blood seven times per day. The quality of control was assessed at the weekly or biweekly clinic visit. Self-monitoring blood glucose data were analyzed for four parameters: mean, interquartile range (variability) distance between the 25th and 75th percentiles, reversals (fluctuation) in median glucose curve, and level of excursion from the median.[10]

The treatment modalities included either diet alone or a combination of insulin and diet. Treatment assignments were determined on the basis of fasting plasma and mean blood glucose levels. Subjects were counseled by a nutritionist in diet management, with a regimen of three meals and four snacks daily. Diet control involved caloric restriction based on maternal body weight.[11, 12] Maternal size was determined by body mass index (body mass index = weight/height^2 in kilograms per meter). Obese patients (body mass index ≥27) were restricted to 25 calories per kilogram of body weight, and nonobese patients to 30 calories per kilogram. Insulin therapy was initiated when fasting plasma glucose, mean blood glucose, or both were >95 mg/dl. Insulin

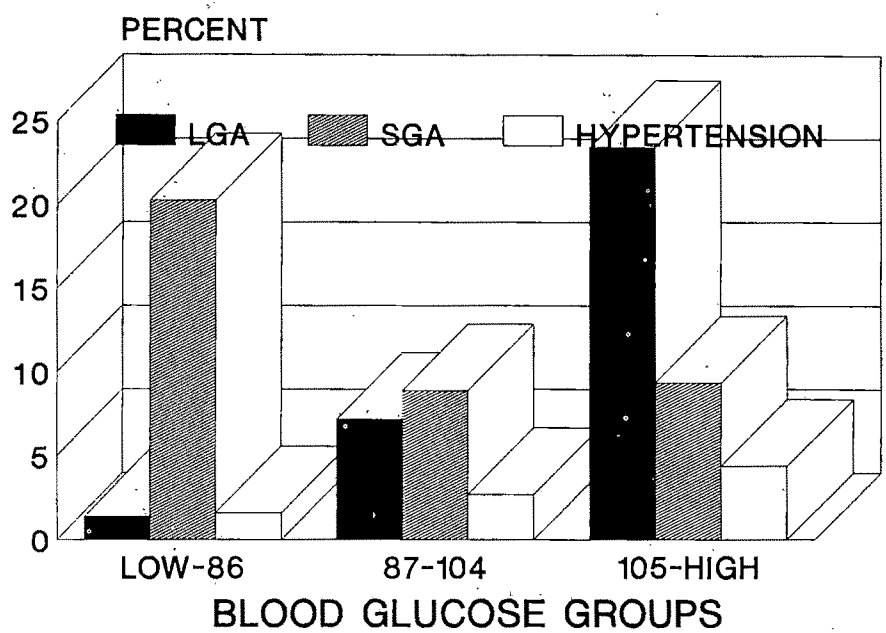

Fig. 1. Association among neonatal size, level of glycemic control, and hypertension.

was administered by multiple injections of regular and NPH insulin synchronized with the diet.[11]

The goal of treatment was to maintain a fasting blood glucose level of 60 to 80 mg/dl, preprandial and bedtime levels of 70 to 90 mg/dl, postprandial levels of <120 mg/dl, and an overall mean <95 mg/dl.

Infants were considered large for gestational age when their birth weight was greater than or equal to the 90th percentile and small for gestational age when their birth weight was less than or equal to the 10th percentile.[13] Clinical data (e.g., last menstrual period), early ultrasonographic result (<20 weeks) when available, pelvic examination, and newborn examination were used to assess gestational age. Neonatal metabolic complications included hypoglycemia (<35 mg/dl), hypocalcemia (<7.5 mg/dl), hyperbilirubinemia (>12 mg/dl), and polycythemia (>65%).

Since we previously identified three clusters on the basis of overall mean blood glucose,[14] in this study they were used to analyze the relationship between level of glycemia and neonatal size. This resulted in three groups: low, ≤86 mg/dl (n = 69); mid, 87 to 104 mg/dl (n = 180); and high, ≥105 mg/dl (n = 85). Data analyses included univariate and bivariate statistical techniques with parametric and nonparametric tests. Categoric data were analyzed with the χ^2 and Fisher's exact tests. Continuous data were analyzed by Student's t test.

Analysis of variance was used to test for differences between the three groups. To determine the extent to which the variables contribute to neonatal size, a stepwise multiple regression was performed. Both tests of significance and the magnitude of the relationships expressed as the variance of the dependent variable that can be accounted for by the independent variable were used to report regression results. Variables contributing 3% of the total variance were considered noteworthy of discussion. In all cases the F values are significant at the 0.01 level or better.

Results

Study sample characteristics. A total of 334 gestational diabetics were identified and participated in this prospective study. They represented a 2.6% incidence of gestational diabetes. The control group was drawn from the group of all women referred for oral glucose tolerance tests from 1985 to 1988; controls were matched for race, obesity, and gestational age at delivery. As shown in Table I, there was a significant difference only in maternal age. Further analysis compared gestational diabetic patient characteristics on the basis of neonatal weight (SGA, appropriate for gestational age (AGA), LGA). The average maternal age was approximately 31 years and was similar for all groups. The mean gestational ages at diagnosis and delivery were comparable. The majority of patients with AGA and LGA infants had been delivered at least once before; the rate of multiparity ranged from 59% to 70%. In contrast, the multiparity rate of the mothers with SGA infants was 38%. Approximately two thirds of patients with LGA infants (71%) were obese and one third (30%) had a previous history of gestational diabetes. This compared to 58% and 11% for SGA, and 49% and 16% for AGA groups, respectively. Characterization of level of glycemic control by means of the ambulatory glucose profile revealed a significant difference between the groups. The mothers with SGA infants were found to have the most stable level of

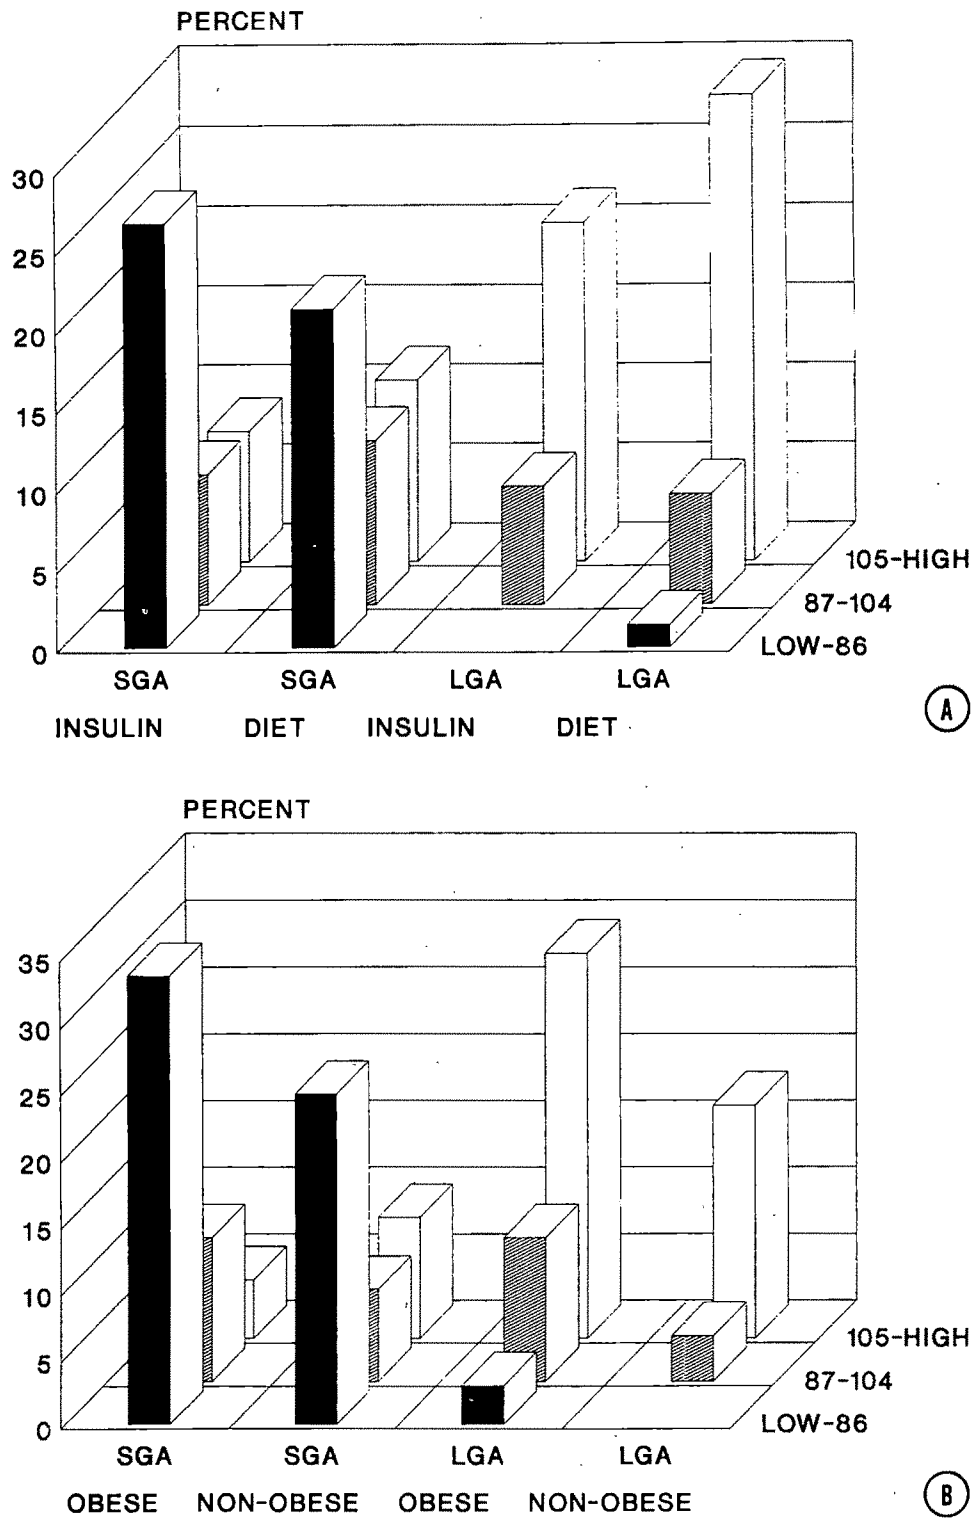

Fig. 2. A, Incidence of LGA, SGA, and treatment modalities. **B,** Incidence of LGA, SGA, and maternal size.

glycemic control (reversals), the lowest mean blood glucose, with a narrow variability indicated by a 27 mg range (Table II).

Association between level of glycemia and neonatal weight. The relationship between level of glycemic control and incidence of SGA and LGA infants is shown in Fig. 1. The relative risk for having an SGA infant in the low (≤86 mg/dl) category (mean blood glucose 81 ± 6 mg/dl) was 2.56 with a 95% confidence interval of 1.24 to 5.29 in comparison with the other groups. No

*SGA versus LGA, $p < 0.006$.

significant difference exists in the two mean blood glucose categories (mid, 87 to 104 mg/dl, mean blood glucose 95 ± 5, and high, ≥105 mg/dl, mean blood glucose 114 ± 7 mg/dl) in the incidence of SGA (8.9% vs. 9.4%, respectively).

In contrast, a relative risk of 20.92 (95% confidence interval, 2.73 to 160.42) for developing LGA infants was found for the high mean blood glucose category when compared with the low mean blood glucose category. In addition, a relative risk of 3.95 (95% confidence interval, 1.86 to 8.40) for developing LGA infants was found between the high and the mid mean blood glucose categories. A relative risk of 2.61 (95% confidence interval, 1.20 to 5.69) was found between the mid and low categories.

Association among level of control, maternal size, treatment modality, and neonatal size. Overall 32% (107) of the 334 participants were managed by diet alone and 68% (227) were treated with insulin. The prevalence of SGA and LGA infants by treatment modality for the three categories of level of glycemic control is shown in Fig. 2, *A*. For patients in the mid mean blood glucose range, the proportion of small infants was unrelated to treatment regimen (10% for diet, and 8% for the insulin groups, p = NS). There was a comparable rate of large infants (6.9% and 7.4%, respectively). No significant difference was found between treatment modalities and the incidence of LGA and SGA infants in the low and high categories of mean blood glucose. Within the low mean blood glucose category, the relative risk for developing SGA vs. LGA infants was 17.31 (95% confidence interval of 2.20 to 60.76). The risk for developing LGA infants within the high category was 2.96 (95% confidence interval of 1.22 to 7.17). Each of these categories unilaterally was found to be significantly different from all other categories ($p < 0.001$).

The data were analyzed to determine the relationship between maternal obesity and LGA and SGA infants. Significantly ($p < 0.04$) more LGA and SGA infants were born to obese (14% and 13%) than nonobese mothers (6% and 10%, respectively).

Fig. 2, *B*, demonstrates that the rate of large infants was significantly higher in the high mean blood glucose category regardless of maternal obesity. Furthermore, in the low mean blood glucose category, a trend was observed for a greater disparity for risk of SGA infants regardless of maternal size. No significant difference in weight change during pregnancy in the three mean blood glucose categories was found.

Pregnancy outcome. Comparison between the control and gestational diabetes subjects for the entire study population revealed a higher incidence of hypertensive disorder in the control group (13% vs. 3%, $p < 0.05$, respectively). No significant difference was found in the incidence of hypertension among the three blood glucose categories in the gestational diabetic patients. The mean weight gain change and primary cesarean section rate (13% vs. 14%) showed no difference between the control and the gestational diabetic subjects. In the control group, an overall incidence of 11.7% SGA and 12.2% LGA infants was calculated. Further analysis between control and low (≤86 mg/dl) category showed the highest incidence of SGA infants (11% vs. 20%) with a relative risk of 1.93 (95% confidence interval of 1.03 to 3.75), and the lowest incidence of LGA infants (12.2% vs. 1.4%) relative risk 6.03 (95% confidence interval of 1.28 to 69.5). In the high mean blood glucose category (≥105 mg/dl), an approximately twofold increase was found in the incidence of LGA infants when compared with the control group (relative risk 2.22, 95% confidence interval, 1.23 to 3.99). Finally, no significant difference was

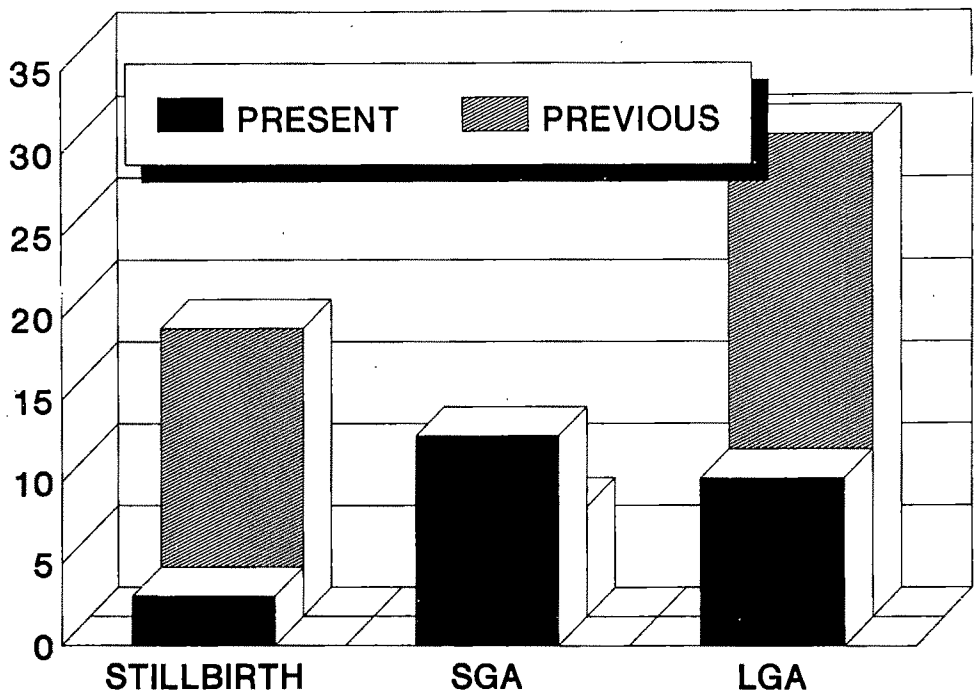

Fig. 3. Pregnancy outcomes: previous versus present pregnancy.

found between the control and mid mean blood glucose category.

The gestational diabetes study population was further stratified on the basis of neonatal weight into three groups: SGA, AGA, and LGA. The neonatal outcomes and selected maternal characteristics by neonatal weight are listed in Table III. Infants were similar with respect to gestational age at delivery (mean, 39 ± 1 weeks) for all patients. Polcythemia was documented in approximately 5% of all neonates, and was most common in the LGA infants ($p < 0.04$).

Hyperbilirubinemia affected 12% of the SGA infants, compared with 4% for each of the other two groups. The incidence of neonatal intensive care unit admission was twofold higher for LGA infants and threefold higher for the SGA infants when compared with AGA infants ($p < 0.03$).

Two stepwise multiple regressions (gestational diabetes and control) were performed to determine the relative contribution of each variable to neonatal size. In the first (gestational diabetes), 21 independent variables were analyzed. Three variables were noteworthy with respect to contribution to neonatal size. Mean blood glucose, weight gain, and gestational age at delivery accounted for 44% of the total variance. Race, parity, hypertension, obesity, and previous large infant, although entered into the regression, did not meet the criteria for inclusion in the regression results. In the second analysis (control), weight gain in pregnancy, body mass index, gestational age at delivery, fasting plasma glucose on glucose tolerance test, and previous LGA infant accounted for 36% of the variance.

Finally, further analysis used patient obstetric history as the comparison for present pregnancy outcome. Previous macrosomia was recorded in 29% of all previous pregnancies. Of these, 78% of the mothers did not have LGA infants in the current pregnancy ($p < 0.02$). There was one stillbirth in this series (3%) of a diet-treated patient at a gestational age of 37 weeks. This is in contrast to an 18% stillbirth rate in previous pregnancies (Fig. 3).

Comment

A key finding in this study is that the incidence of SGA infants of gestational diabetic mothers is significantly related to maternal glucose level. The results further support three distinct mean blood glucose groups: low, ≤86 mg/dl (mean, 81 ± 6 mg/dl) with the highest incidence of IUGR; mid category, 87 to 104 mg/dl (mean, 95 ± 5 mg/dl) comparable to the general population; high category, ≥105 mg/dl (mean, 114 ± 7 mg/dl), which was characterized by the highest rate of LGA infants.

It is widely accepted that complications in the pregnant diabetic (mainly perinatal mortality and congenital malformations) are the consequence of hyperglycemia.[1, 15] However, considerable controversy exists regarding the means for lowering the incidence of perinatal morbidity in mothers with gestational diabetes. The concept that maternal glycemic control can influ-

ence perinatal morbidity was supported by several investigators[14, 15] and refuted by others.[3, 16] The majority of these studies failed to include a control group to reflect a normal population. Additionally, researchers also have debated what criteria constitutes the optimal level of glycemic control. Several key factors contribute to this controversy. Lack of uniformity in the diagnostic criteria creates diverse study populations.

There is inconsistency in the definition of large infants. Some investigators define LGA infants as those with birth weights greater than the 90th percentile, using divergent growth curves, whereas others define macrosomic infants as those weighing >4000 to 4500 gm. The addition of LGA infants contributes to the incidence of infants weighing >4000 gm. Therefore the relatively high proportion of affected infants may remain unrecognized and enhances the scope of the problem.

Furthermore, there is lack of agreement regarding treatment criteria for the patient with gestational diabetes (e.g., insulin initiation) and the appropriate method to verify the accuracy of the glucose data (e.g., frequency, method of testing, and patient compliance). Thus it is problematic to determine the optimal level of glycemia that will maximize pregnancy outcome.[3, 4]

We addressed these issues by maximizing uniformity in our study population by use of the National Diabetes Data Group criteria, adherence to strict calculation and confirmation of gestational age and treatment of all patients with the same protocol using memory-based reflectance meters to assure accurate and reliable data. The standard growth curve comparable to our general population was used. In addition, a matched control from our normal population was chosen to remove selection bias.

The results strongly support the efficacy of stringent metabolic control for the reduction of the incidence of LGA infants. The data further demonstrate that a relationship exists between level of glycemic control and neonatal outcome. The fact that mean blood glucose explained 26% (of total 44% variance) of the contribution to neonatal size further underscores the significance of tight glycemic control. In this group of patients, optimal control was achieved in 75%, and only 25% (high mean blood glucose category) experienced fluctuations in level of control during the study period. This deviation from optimal control for the small number of patients probably accounts for the predictability between mean blood glucose and neonatal size.

The low mean blood glucose category resulted in a high incidence of IUGR (20%). Could this finding be explained by the presence of hypertensive disorder, a factor well known to be associated with SGA infants? The overall incidence of hypertensive disorder in our diabetic subjects was 3%, with the lowest incidence in the low mean blood glucose group (1.6%).

In contrast, the incidence of SGA infants remains virtually the same in the mid and high groups (9% overall). Thus it appears that a mean blood glucose level <87 mg/dl increased the incidence 2.55-fold for the development of IUGR, resulting in a high incidence of neonatal intensive care unit admissions, and a higher incidence of respiratory distress syndrome.

Another concern with previous studies is the failure to analyze separately the obese and nonobese mothers with respect to neonatal outcome. Evaluation of the effect of treatment modalities and maternal obesity on the incidence of SGA infants revealed that the risk appears to be directly related to mean blood glucose levels with two points of demarcation: 87 and 105 mg/dl. The first level signals the risk for IUGR and the second the risk for macrosomia.

Previous studies[3] suggested a high incidence of repeat occurrence of large infants in mothers with a previous history of macrosomia. We found that 78% of the mothers with gestational diabetes who had at least one previous macrosomic infant completed the current pregnancy with an AGA infant. Furthermore, tight verified metabolic control was achieved in 75% of our diabetic patients.

In summary, there is little doubt that absence of insulin in fetal circulation is associated with severe fetal growth retardation. It is also well recognized that macrosomia is a consequence of fetal hyperinsulinemia. Although multiple risk factors are cited as plausible causes for alteration in fetal growth, it appears that level of glycemic control plays a major role. Thus undertreatment and overtreatment of diabetic individuals can result in iatrogenic growth-retarded or macrosomic fetuses. Furthermore, targeting the level of glycemic control to a range of 87 to 104 mg/dl (mean, 95 ± 5 mg/dl) will result in neonatal size comparable to the general population.

Maternal hemoglobin F levels may have an adverse effect on neonatal birth weight in pregnancies with sickle cell disease

Akolisa Anyaegbunam, MD, Henny H. Billett, MD, Oded Langer, MD, Lois Brustman, MD, Claudia Berger, BA, Linda Wyse, MD, Ronald L. Nagel, MD, and Irwin R. Merkatz, MD

Bronx, New York

A total of 26 patients with sickle cell disease were followed up through 32 pregnancies. There was no correlation between days in hospital or number of painful crises and either birth weight or birth weight percentile. The number of dense irreversibly sickled and least deformable cells was negatively correlated with birth weight percentile ($r = -0.63$, $p < 0.01$). Patients' initial hemoglobin levels were positively correlated with birth weight percentile ($r = 0.52$, $p < 0.004$). Hemoglobin F, on the other hand, was significantly inversely correlated with birth weight percentile. Nine pregnancies with small-for-gestational-age infants had an average hemoglobin level of 9.1% ± 4.5%. In contrast, patients who were delivered of appropriate-for-gestational-age infants (23 pregnancies) had an average hemoglobin F level of 3.6% ± 2.9% ($p < 0.01$). We conclude that total hemoglobin levels and dense cells are correlated with birth weight percentile; moreover, the higher the maternal hemoglobin F levels the higher the risk of small-for-gestational-age infants. We speculate that although high hemoglobin levels may be beneficial to the fetus, high maternal hemoglobin F levels could increase the desaturation of non-F cells and induce placental obstruction. (Am J Obstet Gynecol 1989;161:654-6.)

Key words: Sickle cell disease, pregnancy, hematology

Sickle cell disease is a clinically heterogeneous disorder with some patients virtually asymptomatic, whereas others exhibit severe disease.[1] The disease may have an adverse effect on fetal growth and a high prevalence of low birth weight babies has been reported.[2] Although the degree of anemia has been shown to influence birth weight percentile, there is a paucity of information with regard to which, if any, hematologic parameters in sickle cell disease influence neonatal outcome. This study attempts to examine this question by investigating the relationship between several hematologic factors and neonatal birth weight percentile.

Material and methods

All pregnant women with sickle cell disease were initially seen in the first trimester of pregnancy. Prenatal visits were scheduled every 2 weeks until 34 weeks' gestation, and then weekly thereafter. Whenever possible, the hematologic parameters used for analysis were those obtained in the previous nongravid state. If the patient was first seen when pregnant, the values obtained on the earliest visit or well after delivery (>2 months) were used.

Table I. Selected patient characteristics

	Mean ± SD
Maternal age (yr)	26.0 ± 4.8
Birth weight (gm)	2754 ± 463.0
Gestational age at delivery (wk)	38.4 ± 1.8
Hemoglobin (gm/dl)	8.4 ± 1.1
Hemoglobin F (%)	5.8 ± 4.3
Dense cells (%)	13.8 ± 10.0
Hospitalization (days)	30 ± 49
Reticulocyte count (%)	12.6 ± 5.1

Complete blood counts were performed on blood drawn into tubes containing ethylenediaminetetraacetic acid and processed within 8 hours on an automated cell counter (Technicon HI, Tarrytown, N.Y.). Isopyknic red blood cell continuous density gradients were performed by the technique previously described by Fabry and Nagel.[3] Density gradients were photographed and the resultant transparencies were evaluated by densitometry. Four fractions (SS1, SS2, SS3, and SS4) were defined with SS1 representing the lightest cells and SS4 representing the densest fraction of sickle cells and containing the major portion of irreversibly sickled cells.

All patients had solubility studies and hemoglobin electrophoreses performed by both cellulose and agar gel electrophoresis. Hemoglobin F was measured by alkaline denaturation. Reticulocyte counts were per-

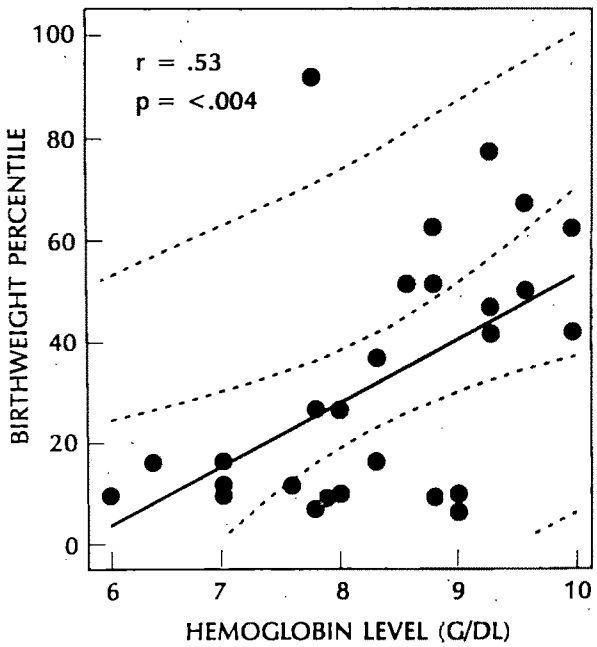

Fig. 2. Regression of initial hemoglobin levels on birth weight percentile.

formed with methylene blue. Bilirubin levels were obtained from routine laboratory serum multichannel analyzers.

Small for gestational age was defined as neonatal birth weight less than the tenth percentile for gestational age.[4]

Distribution statistics, regression analysis, and paired Student *t* tests were performed with a Lotus data base with the Statgraphics statistics program (STSC-PlusWare, Rockville, Md.) on an IBM-AT computer.

Results

A total of 26 patients with sickle cell disease were followed-up through 32 pregnancies. Selected patient characteristics are listed in Table I. The densest and least deformable cells (SS4) were negatively and significantly correlated with birth weight percentile ($r = -0.63$, $p < 0.01$) (Fig. 1). Patients' initial hemoglobin levels were positively and significantly correlated with birth weight percentile ($r = 0.52$, $p < 0.004$) (Fig. 2). Hemoglobin F, on the other hand, was significantly inversely correlated with birth weight percentile ($r = -0.59$, $p < 0.03$) (Fig. 3). Nine of the 32 pregnancies (28%) resulted in small-for-gestational-age births and their mean maternal hemoglobin F level was 9.1 ± 4.5%. In contrast, those patients who were delivered of appropriate-for-gestational-age infants had significantly lower mean hemoglobin F levels 3.6 ± 2.9% ($p < 0.01$).

There was no correlation with days in hospital or number of painful crises and either birth weight or birth weight percentile. In addition, there was no relationship between birth weight percentile and the number of transfusions received during pregnancy, reticulocyte count, mean cell volume, serum bilirubin level or lactic dehydrogenase level.

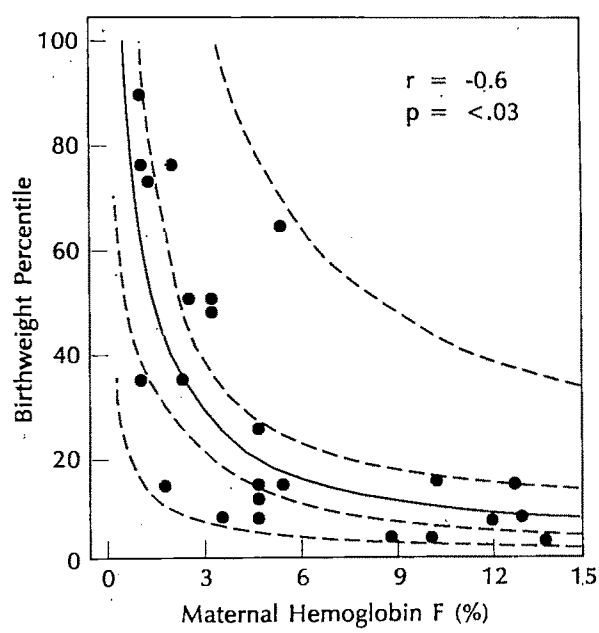

Fig. 3. Regression of maternal hemoglobin F level on birth weight percentile.

Comment

Other investigators have reported that anemic patients tend to have smaller infants with increased risk

of fetal death[5, 6]; hence it is not surprising that pregnant patients with sickle cell disease are delivered of lighter babies. What is surprising is the extent of this positive correlation between birth weight and maternal hemoglobin level, despite the lower oxygen affinity of the sickle hemoglobin secondary to both increase in 2,3-diphosphoglycerate level and intrinsic low affinity of the polymer of hemoglobin S, which should predict better oxygenation than might otherwise be expected for the level of hemoglobin.

Many of the adverse consequences in patients with sickle cell anemia are a result of vasoocclusion induced by sickle cell adhesion and precapillary and capillary obstruction and the subsequent selective trapping of denser sickle cells.[7, 8] In our patient population, the denser and less deformable cells (SS4) were inversely related with neonatal birth weight percentile, which suggests that dense cells may play a role in these phenomena.

The finding that the maternal hemoglobin F level was inversely related to neonatal birth weight was unexpected. High hemoglobin F levels have been associated with decreased hemolysis, higher hemoglobin levels, and fewer dense cells.[9] For most patients with sickel cell anemia, hemoglobin F is unevenly distributed in cells, with some cells containing a large amount of hemoglobin F (F cells) and others with little or no hemoglobin F.[10] Subgroups of patients with sickle cell anemia, the Saudi Arabian and Indian populations and carriers of Senegal haplotype, as well as those with hereditary persistence of hemoglobin F, exist that have higher hemoglobin F values, more F cells, and generally milder disease.[9, 12, 13] It would have been more reasonable to assume that hemoglobin F, with its associated milder disease, would also have a favorable effect on neonatal outcome.

The negative effect of hemoglobin F on birth weight percentile could be explained if the higher hemoglobin F levels in the mother interfere with the ability of the fetus to compete for oxygen at critical stages of development. However, Charache et al.[14] have demonstrated that high affinity hemoglobins with oxygen half-saturation pressure (P 50) levels lower than that of hemoglobin A do not compromise fetal outcome. An alternative explanation is that the delivery of maternal oxygen in the placenta would fall predominantly on the red blood cells that do not contain hemoglobin F because of their lower oxygen affinity. Under these circumstances, and particularly as a result of hemodynamic stasis prevalent in the sinusoids of the placenta, the blood cells that do not contain hemoglobin F would become selectively even more deoxygenated and particularly rigid. The larger the percentage of cells that contain hemoglobin F, the smaller the percentage of low affinity cells and consequently the lower the saturation of these non-F cells. Although fewer, the non-F cells without hemoglobin F in mothers with higher hemoglobin levels will be much more rigid than their counterparts and could induce sludging in general and obstruction of the venular outlets of the sinusoids. This interpretation is in agreement with the data of Charache[14] and our observations of a patient with hereditary persistence of hemoglobin F and 33% hemoglobin F who was delivered of an infant in the 75th percentile. In both instances the hemoglobin is distributed equally in all cells and would not promote selective desaturation of non-F cells. In addition, it may help to explain why transfusion does not appear to be beneficial in pregnancies with sickle cell disease.[2, 15]

We thank Dr. Mary E. Fabry for her help with the gradients, and Kathy Conroy and Fanya Schonbuch for their technical assistance.

Pneumonia during pregnancy: Has modern technology improved maternal and fetal outcome?

Nancy E. Madinger, MD,[a] Jeffrey S. Greenspoon, MD,[b] and A. Gray Ellrodt, MD[c]
Los Angeles, California

The maternal death rate and rate of preterm delivery associated with pneumonia during pregnancy have not decreased since the introduction of antibiotics four decades ago. We retrospectively reviewed 25 cases of pneumonia during pregnancy; these cases occurred among 32,179 deliveries. Medical complications included: bacteremia, 16%; empyema, 8%; atrial fibrillation, 4%; respiratory failure necessitating mechanical ventilation, 20%. Obstetric complications occurring during the pneumonia episode included: preterm labor, 44%; preterm delivery, 36%. A patient with cystic fibrosis died; one stillbirth and two neonatal deaths occurred. Underlying maternal disease was significantly associated with maternal medical complications ($p = 0.023$) and preterm delivery ($p = 0.012$). Significant medical and obstetric complications continue to occur frequently despite modern antimicrobial, tocolytic, and supportive therapy. Underlying maternal disease, including acquired immunodeficiency syndrome and cystic fibrosis, was associated with preterm delivery and neonatal and maternal death. (Am J Obstet Gynecol 1989;161:657-62.)

Key words: Pneumonia, pregnancy, complications, preterm delivery

Pneumonia is an infrequent complication of pregnancy, reported to occur in 1 per 118 to 2288 deliveries.[1-4] It has long been recognized to jeopardize the well-being of both the mother and fetus,[1, 2, 5] although maternal complications have decreased markedly throughout this century.[2-4] The introduction of antibiotics dramatically reduced maternal mortality but did not appreciably affect the rate of preterm delivery.[2]

The spectrum of community-acquired pneumonia in adults has recently been expanded to include several "new" pathogens, including *Legionella pneumophila, Pneumocystis carinii,* and *Chlamydia psittaci* TWAR strain.[6, 7] Additionally, an increasing proportion of pneumonias are secondary to gram-negative organisms, while a declining incidence of *Streptococcus pneumoniae* and *Staphylococcus aureus* has been noted.[7]

Women with chronic respiratory diseases and women who are immunocompromised (from infection, malignancy, or chemotherapeutic agents) are now surviving into reproductive years and are attempting pregnancy. Respiratory infections commonly encountered in such patients may lead to an increase in pneumonias during pregnancy, which may differ from the community-acquired pneumonias described in adults. The impact of this group of patients on the incidence and type of pulmonary pathogens in an obstetric population has not been systematically described. Previous studies of pneumonia during pregnancy either were conducted before the recognition of unusual pathogens that cause pneumonias or consisted of isolated case reports.[8-11] We reviewed all cases of pneumonia in pregnant patients admitted to a university-affiliated, community hospital to determine if the natural history of this medical complication of pregnancy has changed in recent years.

Methods and material

The records of 25 patients with a diagnosis of pneumonia and pregnancy admitted to Cedars-Sinai Medical Center (CSMC) from January 1983 to March 1988 were reviewed. This study was approved by the Human Research Review Committee at CSMC. CSMC is an 839-bed community hospital serving both private and health maintenance organization patients. Patients were identified by a computerized search of medical center records accessed by discharge diagnosis according to the International Classification of Diseases, 9th revision, Clinical Modification (ICD-9-CM).

The criteria for inclusion in the study included: (1) clinical syndrome compatible with pneumonia (pulmonary symptoms and/or fever), (2) radiographic evidence of a pulmonary infiltrate, (3) absence of another noninfectious process that would account for the findings, and (4) time course consistent with community-acquired pneumonia.

Twenty-four of the 25 cases of pneumonia during pregnancy were identified by computer search. Cases incorrectly coded or misclassified as pneumonia, i.e., the physician selected a diagnosis not substantiated by

Table I. Demographic information

	Range	*Mean ± SD*
Age (yr)	15-38	28.5 ± 6.1
Gravidity	1-9	3.6 ± 2.3
Parity	0-5	1.4 ± 1.4
Gestational age at time of admission (wk)	21-39	30.8 ± 5.2
Gestational age at time of delivery (wk)	25-41	35.2 ± 5.0
Maternal hospital stay (days)	3-35	10.0 ± 8.4

the medical record, were not included. One additional case, involving a patient with acquired immunodeficiency syndrome (AIDS), was identified only by alternate sources and is included among the 25 cases.

The charts were abstracted and data entered into the MR-TOD (Retriever Data Systems, Seattle, Washington) data base for analysis. Contingency table analysis was performed with Fisher's exact test or Student's *t* test. All cases were reviewed by two of the authors.

An etiologic agent of pneumonia was assigned if any one of the following criteria were fulfilled: (1) positive blood culture for a known pulmonary pathogen in the absence of another source (when the culture results from blood and sputum were inconsistent, the case was classified according to the blood culture result); (2) sputum culture; (3) viral culture; (4) histologic or cytologic findings from material obtained by bronchoscopy. Patients were categorized as having an unknown cause if a Gram stain was available without confirmatory culture or if sputum culture was incompatible with the clinical course. For example, in a patient whose sputum was colonized with *Haemophilus influenzae,* the illness was cured with erythromycin.

The microbiologic evaluation was deemed inadequate if sputum Gram stain, sputum culture, and blood culture were not obtained. The designation "underlying maternal disease" included patients with asthma, cystic fibrosis, AIDS, and severe pregnancy-induced hypertension.

Results

Demographics. Twenty-five patients with pneumonia during pregnancy were identified. During the 63-month study period there were 32,179 deliveries, yielding an incidence of 0.78 per 1000 deliveries (1 case per 1287 pregnancies). Demographic information is shown in Table I. The racial background included 13 white, 10 black, and 2 Hispanic women. No cases were identified during the first trimester of pregnancy. Underlying maternal disease was present in 6 of 25 (24%) patients: two had asthma; one had cystic fibrosis; one had AIDS; two had severe pregnancy-induced hypertension.

Table II. Pathogenic organisms causing pneumonia during pregnancy

	No.	*%*
Streptococcus pneumoniae	4	16
Haemophilus influenzae	2	8
Pseudomonas aeruginosa	1	4
Influenza A	1	4
Pneumocystis carinii	1	4
No pathogen identified	11	44*
Inadequate microbiologic evaluation	5	20
Total	25	100

*Including two patients with gram-positive cocci in the sputum and a clinical course typical for *Streptococcus pneumoniae* and one patient with viridans *Streptococcus* bacteremia.

Eight patients smoked tobacco and five abused alcohol and/or illicit drugs; only one patient used a parenteral route of drug administration. No identifiable relationship was found between outcome (maternal medical complication or preterm delivery) and the following parameters: age; race; obstetric history; tobacco, drug, or alcohol abuse; or presenting symptoms. Although the mean hospital stay was 10 days, more than half of the patients were discharged within 1 week.

Diagnosis. All patients in the study group had presenting symptoms and/or signs suggesting pneumonia; however, the diagnosis of pneumonia was initially made in only 20 of 25. Two patients had preterm labor with prominent peritoneal signs compatible with an acute condition in the abdomen and underwent emergency appendectomy. In both cases the appendix was normal, and pneumonia was diagnosed as the cause of illness after operation. Pyelonephritis and preterm labor were the initial diagnoses in one patient, and two additional patients had preterm delivery soon after admission and pneumonia was diagnosed the next day. A delay in the diagnosis of pneumonia resulted in inadequate collection of culture specimens, and therefore no pulmonary pathogens were identified in this group.

Microbiology. The cause of pneumonia was determined in 9 patients (Table II). The most common pathogen was *Streptococcus pneumoniae* (four cases); two were identified by sputum culture and two by blood culture. *Haemophilus influenzae* was identified in two patients. In one who had respiratory failure, blood, pleural, and pericardial cultures were positive. This case was reported elsewhere.[12] The single case of *Pseudomonas aeruginosa* pneumonia occurred in a patient with cystic fibrosis who had a long history of similar infections. *Pneumocystis carinii* pneumonia was the initial clinical illness in the patient with AIDS.

Eleven of 25 patients (44%) had no pathogen identified. Serologic studies for causes of atypical pneumonia were completed in only one of these patients.

Two patients were presumed to have *Streptococcus pneumoniae* on the basis of sputum Gram stain, clinical presentation, and response to appropriate antibiotics. Three cases were most consistent with *Mycoplasma pneumoniae,* although confirmatory serologic studies were not done. Although one patient had bacteremia caused by a viridans *Streptococcus,* this organism was not considered to be the pulmonary pathogen. Five patients (20%) had an inadequate microbiologic evaluation. Antibiotics empirically used with a successful clinical cure in patients without an etiologic diagnosis included erythromycin, ampicillin, cefazolin, and cefuroxime. No adverse antibiotic effect was noted in any case.

Maternal complications. All of the major complications occurred in 12 patients (Table III). Severe maternal disease was a significant risk factor for medical complications. Five of 6 (83%) patients with underlying maternal disease developed maternal medical complications of pneumonia, compared with 5 of 19 without underlying maternal disease ($p = 0.023$). Preterm delivery during pneumonia occurred in 2 of 4 women with bacteremia, in 5 of 6 women with mechanical ventilation of the lungs, and in 5 of 6 women with underlying maternal disease.

The single maternal death occurred in a 20-year-old woman, gravida 2, para 0, with one elective abortion; this woman had cystic fibrosis and pulmonary function tests predicted a poor maternal pregnancy outcome.[13] She developed an overwhelming *Pseudomonas* pneumonia with hypoxia and an intractable respiratory acidosis despite maximal ventilatory support. Arterial blood gas values with an inspired oxygen concentration of 60% were pH 7.25, P_{CO_2} 75 torr, P_{O_2} 58 torr, bicarbonate 32 mEq/L, oxygen saturation 84%. At 29 weeks' gestation, a cesarean section was performed during the terminal stage of her illness. Her infant developed hyaline membrane disease and died of *Pseudomonas* sepsis in the neonatal period.

Obstetric complications. Obstetric outcomes in 21 of the 25 patients for whom complete delivery data were available are shown in Fig. 1. Eleven patients (44%) had preterm labor. Preterm labor was common both in patients with underlying maternal illness (2 of 6) and in those without underlying maternal illness (9 of 19). The proportion of patients with preterm labor was not different between groups ($p = 0.66$).

Five of the 11 (45%) had successful tocolysis. Two of these 5 and 2 patients who did not require tocolysis were lost to follow-up and are not included in Fig. 1. Two patients had preterm delivery during a later hospitalization despite successful tocolysis and clinical cure of pneumonia during the initial admission. One of these patients had pyelonephritis, which was cured at the time pneumonia developed; the other had a twin pregnancy and required a cervical cerclage for an incompetent cervix while she was ill with pneumonia. She was delivered of her infant 50 days later with clinical evidence of abruptio placentae.

Table III. Major medical and obstetric complications

Complication	*No. of patients*	*%*
Bacteremia	4	16
Empyema	2	8
Mechanical ventilation	5	20
Pneumothorax	1	4
Pericardial tamponade	1	4
Atrial fibrillation	1	4
Appendectomy	2	8
Maternal death	1	4
Neonatal death	3	12
Preterm delivery during active pneumonia	9	36

Severe maternal disease was a significant risk factor for preterm delivery during the episode of pneumonia. Preterm delivery during the course of pneumonia occurred in 5 of the 6 patients with underlying maternal disease compared with 4 of 19 without underlying maternal disease ($p = 0.012$). Delivery data were unavailable for four patients, including one with underlying disease, asthma.

Although 12 of the febrile patients had fetal tachycardia (fetal heart rate >160 beats/min) when they were initially seen, this appeared to be unrelated to outcome. Fetal distress during the episode of pneumonia was observed in only one case, in a patient with AIDS, who had an intrapartum stillbirth of a 25-week fetus.

Perinatal complications. There was one stillbirth and two neonatal deaths in this series. The perinatal death rate in this study was 3 of 26 (including one set of twins), or 115.4 per 1000 births. The patient with cystic fibrosis whose neonate died was described above. One patient with asthma, who required mechanical ventilation, developed preterm labor and was delivered at 26 weeks' gestation. The neonate died of complications of prematurity.

Comment

Historical perspective. Historically, pneumonia during pregnancy was thought to occur more frequently and to be more severe than in the nonpregnant population. In 1939, Finland and Dublin[1] described pneumococcal pneumonia in the preantibiotic era and noted that 13% of cases of pneumonia occurring in women of reproductive age were among pregnant patients. The incidence of pneumonia among hospitalized obstetric patients was 0.63%. Bacteremia and mortality were highest in the obstetric cases, and maternal mor-

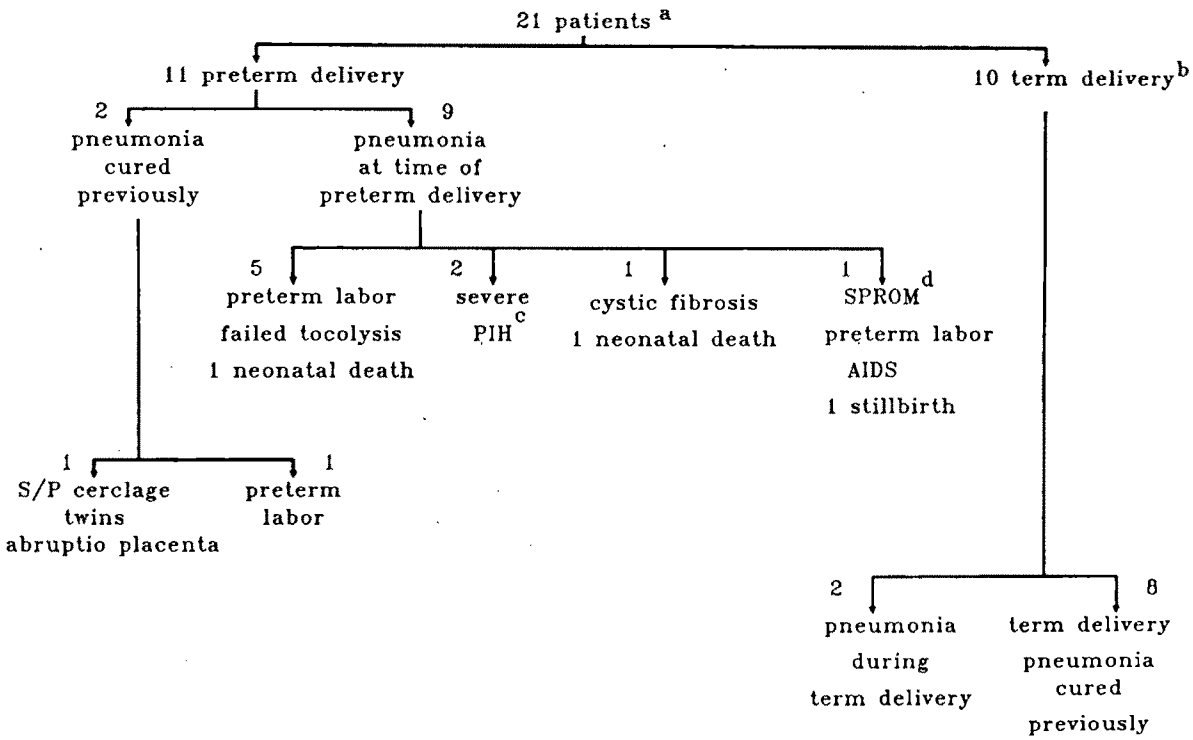

Fig. 1. Flow diagram of the obstetric outcomes of patients with pneumonia during pregnancy. *a*, The figure does not include four patients who were discharged undelivered after the pneumonia was cured and then were lost to follow-up. *b*, Includes one patient who was delivered at 36 weeks during an episode of pneumonia. *c*, Severe pregnancy-induced hypertension was the indication for preterm delivery in both patients. *d*, Spontaneous preterm premature rupture of the membranes occurred during the episode of preterm labor.

tality was greatest in patients who were delivered of their infants or were near term.

Oxorn[2] stated that mortality declined significantly with the advent of antibiotics. However, preterm delivery was unaffected by the availability of antimicrobials and involved nearly half the cases. Mortality was again felt to be increased in those patients who delivered or were near term.

In 1965, Hopwood[3] reported 23 cases from a military-based population and noted an association of tobacco use and the incidence of pneumonia. The Collaborative Perinatal Study[14] provides the largest prospective series of pneumonia during pregnancy. The perinatal death rate was 7 in 119 births (58.8 per 1000 births).

Benedetti et al.[4] reported a decline in the incidence of pneumonia, a reduction in preterm delivery, and a major decrease in maternal mortality in 1982. The overall improvement was attributed to modern obstetric care and a population who presented early in the course of disease and received antibiotics promptly.

Maternal complications. The high complication rate in our series does not differ from rates in other reports published during the modern era (Table IV). Maternal death rates declined after the introduction of antibiotics but have remained essentially unchanged since 1955. The rate of preterm delivery is unaltered over the past three decades. One explanation for this lack of change may be that the population being described is different. Previous studies did not mention patients requiring mechanical ventilation, suggesting that our patients may have been more severely ill. Certainly, at least five patients would have died during the episode of pneumonia if ventilatory support and other critical care modalities had been unavailable.

Moreover, this series included several patients with chronic illness who would not have been part of an obstetric population in the past. We report one death involving a patient with cystic fibrosis who had prognostically ominous Shwachman-Kulczycki clinical scores and pulmonary function tests.[13] She had been counselled about the potentially adverse outcome of pregnancy and had undergone an elective abortion of her first pregnancy. Her decision to continue her second pregnancy resulted in a tragic outcome for both the mother and the neonate. In general, patients with mild to moderately severe cystic fibrosis apparently tolerate pregnancy, and the subgroup at risk for deterioration can be clinically identified and counseled before conception.[13]

The patient with AIDS survived her first episode of *Pneumocystis carinii* pneumonia as well as pregnancy, in contrast to most case reports of maternal AIDS in pregnancy.[9-11] Additional maternal deaths caused by pneumonia in pregnancy may occur as concomitant infection with the human immunodeficiency virus becomes more prevalent in our society. Preterm labor and failure of tocolysis are common in pregnant patients with AIDS and active pulmonary disease. Perimortem cesarean section in terminally ill patients may be appropriate under some circumstances.

Obstetric complications. Previous reports described the rate of preterm delivery but not that of preterm labor (although the two rates may have been similar before the routine use of effective tocolytic agents). Although Benedetti et al.[4] noted that preterm delivery was less frequent in their series than in previous reports they did not state if this was the result of the use of tocolytic therapy. In our study 11 of 25 patients (44%) had preterm labor; only 5 of 11 (45%) had successful tocolysis. The reason for the high rate of preterm labor associated with pneumonia or other infections outside of the reproductive tract is not well understood. The cervicovaginal microflora and/or the host's inflammatory response to infection have been implicated as a cause of preterm labor. One postulated mechanism is the local production of prostaglandins.[15] A similar inflammatory response to infection in the lung might produce prostaglandins that could circulate to the uterus and produce preterm labor. It is conceivable that pneumonia triggers a process that leads to preterm labor early in the course of pneumonia and is not affected by antibiotics or tocolytics.[16]

Perinatal complications. The perinatal death rate of 115.4 per 1000 births is higher than that reported by the Collaborative Perinatal Study despite major technologic advances in diagnosis, monitoring, supportive care, and treatment of premature neonates. The two neonatal deaths in this series resulted from complications of preterm delivery. The stillbirth occurred in a 25-week fetus; intervention was considered inappropriate in this case because of immaturity. All three perinatal deaths occurred in pregnancies complicated by underlying maternal disease, pneumonia, and preterm delivery.

Study design. Although all the cases of pneumonia during pregnancy that we identified were reviewed, we recognize the limitations of retrospectively retrieving cases via ICD-9-CM codes. For this reason we searched alternate sources and were able to identify only one additional case. We were aware of several cases that were also identified by the search. There were no missing medical charts of the pneumonia episode, which might have resulted in misleading conclusions.[17]

The retrospective design of this and other reports of pneumonia may provide a biased description of the etiologic agents causing pneumonia because there may be variation in the completeness of the microbiologic evaluation. There was no systematic attempt to determine the cause of atypical pneumonia in our series of patients. The proportion of patients without an identifiable agent in our study, 64%, is higher than the proportion reported in prospective studies of nonpregnant adults, as frequently as 57%.[18] As in the study of Benedetti et al.,[4] the most common pathogen in our series was *Streptococcus pneumoniae.* Even the frequency

of pneumococcal pneumonia may be underestimated because this is a fastidious organism that may not grow from the sputum culture and therefore would not be identified unless seen on Gram stain or identified from blood cultures. Conversely, there is a danger of falsely attributing the cause of pneumonia to *Streptococcus pneumoniae* because the sputum of 35% to 60% of normal individuals may be colonized with this organism.[19] In view of changing trends in the causes of adult pneumonias, it would be best to interpret our results in terms of the wide range of pathogens that cause pneumonia during pregnancy but not to assign a specific frequency to each agent.[7]

Only one pregnant patient received outpatient treatment of pneumonia before admission. Because preterm labor is a frequent complication of pneumonia, initial in-patient evaluation and treatment may be prudent. The evaluation might include Gram stain and culture of sputum,[20] blood cultures, skin testing for tuberculosis and coccidioidomycosis, serologic tests for respiratory pathogens, and viral cultures. More aggressive methods of obtaining a diagnosis, such as bronchoscopy, are warranted in some patients. Until a prospective study of pregnant patients is undertaken, empiric antibiotic coverage should be based on data collected from the nonpregnant population with similar underlying diseases.

Although the incidence of pneumonia during pregnancy remains low, significant morbidity occurs in many of these cases, especially if the mother suffers from underlying illness. In 40% of the cases reviewed in this series, patients experienced potentially life-threatening complications such as sepsis, respiratory failure, and cardiac tamponade. In addition, preterm labor and delivery remain a major problem, despite the use of modern tocolytic agents.

Comparison of predelivery versus postdelivery Kleihauer–Betke stains in cases of fetal death

John Owen, MD, Charles M. Stedman, MD, and Tommy L. Tucker, MT(ASCP)
Birmingham, Alabama

A prospective study was undertaken to determine whether the delivery process could introduce a significant amount of fetal cells into the maternal circulation in patients with a fetal death. Sixty-six cases of fetal death were studied over a 39-month period. All patients had both predelivery and postdelivery Kleihauer-Betke stains performed. Of these, three (4.6%) had a massive fetomaternal hemorrhage. None of the postdelivery stains showed evidence of a significant fetomaternal hemorrhage unless results of the antepartum stain had also been positive. We conclude that the delivery process itself does not simulate a massive fetomaternal hemorrhage in cases of fetal death. (AM J OBSTET GYNECOL 1989;161:663-6.)

Key words: Fetomaternal hemorrhage, fetal death, Kleihauer-Betke stain

The association between massive fetomaternal hemorrhage and poor perinatal outcome has been well described.[1,2] Fetomaternal hemorrhage has been reported to occur in patients with various obstetric complications, but may also occur without a recognizable antecedent event. Nevertheless the exact pathophysiology of this disorder remains obscure. Previous series[3] have reported that the incidence of massive fetomaternal hemorrhage in otherwise unexplained cases of fetal death is as high as 14%, while the incidence of fetal death from massive fetomaternal hemorrhage is <0.1%.[2] However, most series included patients who only had a postpartum fetal cell stain. Hence, fetal cells could have entered the maternal circulation during delivery. We therefore sought to determine whether the delivery process could simulate a massive fetomaternal hemorrhage by introducing fetal cells into the maternal circulation after the death had occurred.

Material and methods

Since November 1985 a protocol has been in effect for the evaluation of women with a fetal death at ≥24 weeks' gestational age. This evaluation includes a fetal cell stain of the maternal blood before and after delivery. Fetal cell stains were performed using the Simmler acid elution kit according to manufacturer directions. A minimum of 5000 cells on each slide were counted, and positive control slides were made with each maternal sample batch by means of stored cord blood samples to assure adequate stain efficiency.

The predelivery maternal blood samples were collected into vials containing ethylenediaminetetraacetic acid at the time of diagnosis (n = 4), at the time of admission for delivery (n = 56), or both (n = 6). The postpartum samples were collected in similar fashion within 4 hours of delivery. All samples were processed and interpreted by one of the physician-authors within 72 hours of collection. If processing could not be performed immediately after collection, the blood was stored at 3° C.

In each case clinical information from the antepartum, labor, delivery, and postpartum records was reviewed by one of the physician-authors for factors that may have contributed to the fetal death. If a direct cause-and-effect relationship could be established (i.e., massive abruptio placentae), the case was deemed certain. If complications that may have caused the fetal death were present, the case was termed possible (i.e., hypertensive disease), and if no cause or association could be found, the case was assigned an unknown classification. Since autopsies, placental microscopic examinations, and genetic studies were encouraged but inconsistently obtained, this information was not used in the clinical assignments of causality.

To estimate the magnitude of the fetomaternal hemorrhage expressed as a proportion of the total fetoplacental blood volume, the fetoplacental blood volume was calculated with a combination of the formula established by Morris[1]—Fetoplacental blood volume = 162 ml/kg—and the birth weight. Then the volume of fetal cells in the maternal circulation was calculated by use of the following formula[3]:

$$\frac{\text{No. of fetal cells}}{\text{No. of maternal cells}} \times 2400 = \text{Volume of fetal cells in maternal circulation (ml)}$$

Assuming a nominal baseline fetal hematocrit of 50%, the proportion of the estimated fetoplacental blood volume from an acute hemorrhage into the maternal circulation is twice the volume of fetal cells detected from the fetal cell stain divided by the estimated fetoplacental blood volume. Although this is only a crude estimate because of the assumptions made in the calculations, it may serve as a gauge of the severity of the hemorrhage in a more meaningful fashion than the simple calculation of the volume of fetal cells in the maternal circulation.

When appropriate, data are expressed as the mean ± 1 SD. Confidence limits for binomial proportions are derived from the exact computational method.

Results

A total of 66 patients entered the study. The mean maternal age was 24 years (range, 13 to 40 years) with a racial distribution of 62% black and 38% white women. There were 35 primiparous and 31 multiparous women. The mean gestational age at diagnosis was 34 weeks; 13 patients were between 24 and 30 weeks, 31 were between 31 and 36 weeks, and the remaining 22 women were ≥37 weeks' gestation. Sixty-four of the 66 patients came either to the clinic for their obstetric care or to the labor suite for acute care and were found to have a fetal demise. One patient suffered a fetal death on the antepartum ward, and there was one intrapartum fetal death.

Ten patients were assigned to the certain group, 29 to the possible group, and 27 to the unknown group. The causes and associations discovered for those in the last two groups are listed in Table I. Of the 27 patients with an unknown classification, three (11.1%, 95% confidence limits 2 and 27) had evidence of a massive fetomaternal hemorrhage on their antepartum stains.

The first patient, a 28-year-old, para 0-0-2-0, white female woman, was seen near term with unreliable gestational criteria, spontaneous contractions, and absent fetal movement for 2 days. An ultrasonographic examination documented the absence of fetal cardiac activity. Except for smoking less than 10 cigarettes a day during her pregnancy, no antepartum risk factors could be established. At the initial cervical examination, the cervix was dilated 5 cm and labor was complicated by amnionitis. A fetal cell stain on admission showed an 8.7% fetomaternal hemorrhage, equivalent to 209 ml of fetal cells or approximately 160% of estimated fetoplacental blood volume. In addition, the rhesus typing returned Du positive. Because of the magnitude of the fetomaternal hemorrhage, we postulated that rhesus-positive cells from the fetus may have caused the Du factor to appear falsely positive. Therefore she was treated with eight vials of Rh immune globulin. The postpartum stain showed 6.6% fetal cells. Rhesus typing and an indirect Coombs test repeated 1 year later demonstrated that she was Du-negative and had not been become sensitized from the transfusion of rhesus-positive fetal cells. She was delivered of a 2070 gm female stillborn infant with no obvious anomalies. An autopsy was declined, and no placental pathologic examination was performed. No cause for the fetal death could be established.

The second patient was a 23-year-old, para 0-0-1-0, rhesus-positive, white woman, who was seen at 36 weeks' gestation with absent fetal movement for 7 days. An ultrasonographic examination confirmed the absence of fetal cardiac activity. The only identifiable risk factor was maternal smoking of <20 cigarettes per day. Labor was induced with oxytocin, and she was delivered of a macerated, but otherwise normal-appearing, 2785 gm male stillborn infant. The admission fetal cell stain showed a fetomaternal hemorrhage of 3.8% corresponding to 91 ml of fetal blood or approximately 40% of the estimated fetoplacental blood volume; the postpartum stain showed 2% fetal cells. An autopsy was declined, but placental pathologic examination revealed hemorrhagic endovasculitis, which has been shown to be associated with poor perinatal outcomes[6]; however, a consistent association with fetomaternal hemorrhage has not yet been established.

The third patient was a 21-year-old, para 1-0-0-1, rhesus-positive, black woman who was seen at 42 week's gestation complaining of absent fetal movement for 1 day. After ultrasonographic confirmation of the fetal death, she was discharged home to await spontaneous

labor. Two days later she was delivered of a 2850 gm female stillborn infant with no obvious anomalies. An autopsy and placental pathologic examination failed to reveal another cause for the fetal death. The fetal cell stain at diagnosis showed 7.1% fetal cells. This was equivalent to 170 ml of fetal cells, or approximately 74% of the estimated fetoplacental blood volume. The fetal cell stains performed 2 days later on admission and again post partum showed 4.8% and 6.1% fetal cells, respectively.

A total of 63 patients demonstrated no evidence of a significant fetomaternal hemorrhage (<10 fetal cells per 5000 maternal cells), and these were considered as negative. Therefore in an unselected series of 66 patients with a fetal death at ≥ 24 weeks' gestation, three (4.6%, 95% confidence limits 2 and 12) were attributable to a massive fetomaternal hemorrhage. The incidence of the delivery process simulating a massive fetomaternal hemorrhage was 0 in 63 cases (0%, 95% confidence limits 0 and 6).

Comment

Although the exact cause of massive fetomaternal hemorrhage remains poorly defined, its association with perinatal morbidity and mortality has been well documented. A number of newer methods have become available for the detection of fetal cells in the maternal circulation, but the acid elution stain still remains a popular technique.[7] Although its use has been questioned for the precise quantification of fetomaternal hemorrhage, it is rapidly performed with commercially available reagents, and it has been well described in the obstetric literature.

Although it has generally been accepted that the finding of a massive fetomaternal hemorrhage meant that the cause of fetal death was simple exsanguination, this has never been conclusively demonstrated. However, evidence that strongly suggests this as the cause includes the reports of live-born infants with severe anemia and abnormal fetal heart tracings in association with massive fetomaternal hemorrhage.[1, 8] However, the possibility that fetal cells may enter the maternal circulation in large quantities after fetal death has already occurred has never been adequately studied. We were unable to demonstrate this effect in any of our five patients who had a negative antepartum stain at diagnosis and another stain performed at the time of admission for delivery. Similarly, the effects of delivery on the process of fetomaternal hemorrhage after fetal death has remained a viable question. After fetal death has occurred normal clotting mechanisms are activated, autolysis commences, and the hydrostatic pressure in the fetal compartment is lost. We postulate that these factors preclude the entry of a large quantity of fetal cells into the maternal circulation.

Although the precise definition of the term massive fetomaternal hemorrhage remains elusive, its effects on the fetus are probably a result of both the magnitude and chronicity of the blood loss as well as the current fetoplacental blood volume. The finding of 25 ml of fetal red blood cells in the maternal circulation is more significant at 20 weeks' gestation (the entire estimated fetoplacental blood volume) than at 40 weeks' gestation (10% of the fetoplacental blood volume). We would estimate that an acute hemorrhage of 20% or more of the fetoplacental blood volume could be clinically significant, but the minimum hemorrhage required to cause fetal death is not known. A review of six case reports of fetal death from fetomaternal hemorrhage[3, 9] demonstrates a range from 23% to 51% of the estimated fetoplacental blood volume at the time of sample collection, whereas in cases of maternal trauma and poor perinatal outcome, the percentage of the estimated fetoplacental blood volume found in the maternal circulation was between 14% and 34%.[10] However, important variables that can affect the estimation of fetal blood loss with fetal cell stains include the rate of entry of fetal cells into the maternal circulation and the rate at which the fetal cells are cleared, particularly when an ABO or rhesus incompatibility exists. Since the exact time of fetal death can seldom be established, the possibility exists that an exsanguinating hemorrhage could occur and the fetal cells be destroyed before a fetal cell stain is performed. These topics have never been adequately addressed in previous studies on fetomaternal hemorrhage and fetal death. Currently there are insufficient data in the literature to establish the optimum management of a pregnancy complicated by a fetomaternal hemorrhage in which fetal death has not also occurred, although an intrauterine transfusion might be considered if signs of fetal decompensation are present.[11]

We conclude that the incidence of massive fetomaternal hemorrhage in cases of fetal death is low and that the delivery process itself does not simulate a fetomaternal hemorrhage by introducing fetal cells into the maternal circulation. We recommend that a fetal cell stain be obtained in all cases of fetal death to establish the diagnosis of a massive fetomaternal hemorrhage. In addition, careful microscopic examination of the placenta may also be of value and needs further study. However, few data exist to determine the prognosis of future pregnancies in those women who have suffered this condition.

Uterine rupture: Are intrauterine pressure catheters useful in the diagnosis?

M. Hellen Rodriguez, MD, Damon I. Masaki, MD, Jeffrey P. Phelan, MD, and Fidelia G. Diaz, MA

Los Angeles, California

The usefulness of the intrauterine pressure catheter in the diagnosis of uterine rupture was assessed by review of 76 cases of uterine rupture, 39 of which were monitored with an intrauterine pressure catheter. The classic description of a loss of intrauterine pressure or cessation of labor was not observed in any of the patients. However, an increase in baseline intrauterine pressure was observed in four patients with an intrauterine pressure catheter. The increase in pressure was associated with severe variable decelerations such that by itself the intrauterine pressure catheter added little to the diagnosis of uterine rupture. (Am J Obstet Gynecol 1989;161:666-9.)

Key words: Uterine rupture, intrauterine pressure catheter

The intrauterine pressure catheter has the advantage of providing the clinician with quantitative measurements of uterine resting tone as well as the duration and intensity of contractions.[1] Because loss of intrauterine pressure and cessation of labor are thought to be classic signs of uterine rupture,[2] it has been taught that an intrauterine pressure catheter would be helpful in making the diagnosis. As a consequence of this and the fear of possible uterine rupture in patients who undergo a trial of labor after a prior cesarean section, it has become common practice in many institutions to monitor these patients with an intrauterine pressure catheter.

Uterine rupture has been extensively reviewed by several authors.[3-6] However, review of the literature shows there is a scarcity of data that support or disclaim the use of the intrauterine pressure catheter in patients at risk of rupture. In this article the value of the intrauterine pressure catheter in making the diagnosis of uterine rupture is assessed.

Material and methods

This is a retrospective study that consisted of chart and monitor strip review of all cases of uterine rupture at the Los Angeles County–University of Southern California Women's Hospital between June 1979 and April 1988. The definition that was used for uterine rupture was that of Plauche et al., "cases of complete separation of the wall of the pregnant uterus with or without expulsion of the fetus, which endangered the life of the mother and/or fetus. Asymptomatic uterine scar dehiscences were excluded."[6]

The patients in the study were divided into three groups on the basis of the type of uterine monitoring

Table I. Maternal characteristics of each study group

	Group A (n = 8): No uterine monitor	*Group B (n = 29): External tocometer*	*Group C (n = 39): IUPC*

they received. Group A did not have uterine monitoring; these patients went to surgery within 30 minutes of entering the hospital because of fetal or maternal compromise. Patients in group B were monitored with an external tocodynamometer and patients in group C were monitored with a standard open-ended intrauterine pressure catheter. The three groups were compared in terms of fetal and maternal outcome as well as diagnostic signs and symptoms of uterine rupture with χ^2 analysis (or Fisher's exact test for total 2×2 table frequencies <40), one-way analysis of variance, or the Kruskal-Wallis rank test depending on the scale of measurement. After an overall significant result was achieved, pairwise comparisons were conducted with appropriate multiple comparison procedures with $\alpha = 0.05$.

Results

During the study period there were 138,853 deliveries at Women's Hospital. A total of 84 patients (one case per 1653 deliveries) met the definition for uterine rupture. There were 8 patients who were not included in the study because of failure to obtain the complete charts with the monitor strip. Of the 76 patients included in the study, eight patients went directly to surgery (group A), 29 patients had external tocodynamometry only (group B), and 39 had an intrauterine pressure catheter (group C).

Table I presents the maternal characteristics of each group. There is no statistically significant difference between groups with respect to admission characteristics. As expected, no patients in group A received oxytocin or epidural anesthetics because they went immediately to surgery. The number of patients who received oxytocin is significantly higher in group C than that of group B. This is a consequence of our protocol, which strongly encourages the use of an intrauterine pressure catheter in patients who receive oxytocin. The use of epidural anesthetics or the history of a prior cesarean section was not statistically different between the groups.

Table II presents the signs and symptoms that led to the suspicion of uterine rupture. In three patients there was no suspicion of rupture and the diagnosis was made at the time of cesarean section for other indications. One patient in group A who underwent an elective

repeat cesarean section because of a previous classical uterine incision was found to have a prolapsed fetal arm through a rupture of the prior incision. Two patients in group C met criteria for failure to progress and at the time of cesarean section were incidentally found to have ruptured uteri. The most common sign or symptom to uterine rupture in all groups was fetal distress that preceded pain and hemorrhage. None of the patients including those with an intrauterine pressure catheter, demonstrated a loss of uterine tone or cessation of labor. It is of interest that four patients with an intrauterine pressure catheter demonstrated an increase in baseline uterine tone (Fig. 1) from an average of 15 to 35 mm Hg at the time of diagnosis.

Table III presents the maternal and fetal outcomes in each of the groups. The mortality and morbidity for both the infant and the mother are higher in group A and are not significantly different between groups B and C. Therefore the use of the external tocodynamometer versus the intrauterine pressure catheter did not appear to affect the neonatal or maternal outcomes.

Comment

Loss of uterine tone and cessation of labor have been thought to be classic signs in making the diagnosis of uterine rupture. Because the intrauterine pressure catheter provides the clinician with quantitative measurements of uterine activity, its use has been advocated in patients who are at increased risk of uterine rupture such as patients who undergo a trial of labor after a previous cesarean section.

In this study we reviewed diagnostic signs and symptoms of uterine rupture in 76 cases. None of the patients with or without an intrauterine pressure catheter had a decrease in uterine resting tone or cessation of labor. It is noteworthy that four of 39 patients (10%)

with an intrauterine pressure catheter showed an increase of uterine baseline tone. Whether this increase in tone caused or resulted from the uterine rupture remains unanswered. In all four cases the increase in tone was accompanied by severe variable decelerations that led to immediate cesarean delivery. Therefore the information obtained by the intrauterine pressure catheter was not helpful in making the diagnosis of uterine rupture in any of the patients in our study.

In conclusion:

1. The classic description of a decrease in uterine tone or the cessation of labor at the time of uterine rupture was not observed.

2. There is no difference in fetal or maternal morbidity or mortality when an intrauterine pressure catheter is used versus an external tocodynamometer in patients with uterine rupture.

3. Fetal distress occurred in 78% of cases and was the most common finding in uterine rupture.

4. The usefulness of the intrauterine pressure catheter in making the diagnosis of uterine rupture is not supported by this study.

The effect of continuous epidural analgesia on cesarean section for dystocia in nulliparous women

James A. Thorp, MD,[a] Valerie M. Parisi, MD, MPH,[b] Peter C. Boylan, MB,[a] and Dennis A. Johnston, PhD[c]

Houston, Texas

Epidural analgesia in labor is generally accepted as safe and effective and therefore has become increasingly popular. However, little is known regarding the effect of epidural analgesia on the incidence of cesarean section for dystocia in nulliparous women. During the first 6 months of 1987 we studied 711 consecutive nulliparous women at term, with cephalic fetal presentations and spontaneous onset of labor. Comparison of 447 patients who received epidural analgesia in labor with 264 patients who received either narcotics or no analgesia was performed. The incidence of cesarean section for dystocia was significantly greater ($p < 0.005$) in the epidural group (10.3%) than in the nonepidural group (3.8%). There remained a significantly increased incidence ($p < 0.005$) of cesarean section for dystocia in the epidural group after selection bias was corrected and the following confounding variables were controlled by multivariate analysis: maternal age, race, gestational age, cervical dilatation on admission, use of oxytocin, duration of oxytocin use, maximum infusion rate of oxytocin, duration of labor, presence of meconium, and birth weight. The incidence of cesarean section for fetal distress was similar ($p > 0.20$) in both groups. There were no clinically significant differences in frequency of low Apgar scores at 5 minutes or cord arterial and venous blood gas parameters between the two groups. This study suggests that epidural analgesia in labor may increase the incidence of cesarean section for dystocia in nulliparous women. (Am J Obstet Gynecol 1989;161:670-5.)

Key words: Epidural, labor, cesarean section, dystocia, nullipara

The rising cesarean section rate, from 5% to 25% over the past 25 years, has resulted in major cost increases and higher maternal morbidity and mortality without proved benefit to the mother or newborn. One of the major factors in the cesarean "epidemic" is the rise in the incidence of cesarean section for dystocia in nulliparous women. Vaginal delivery after cesarean birth is performed in only a small minority of cases nationwide, and therefore the rise in cesarean section for dystocia in nulliparous women is responsible for a rise in repeat cesarean section in multiparous women. Thus cesarean section for dystocia in nulliparous women represents the single most important factor in the cesarean "epidemic."

The use of epidural labor analgesia also has increased dramatically over recent years, and the effect of epidural analgesia on the incidence of cesarean section is controversial. In the large body of literature concerning epidural analgesia in labor, there are suprisingly few controlled studies that address the effects of epidural analgesia on cesarean section rates.[1-4] One controlled, retrospective study demonstrated an increased incidence of cesarean section associated with epidural analgesia in labor.[1] To our knowledge, there are no controlled studies that specifically examine the effect of epidural analgesia on the incidence of cesarean section for dystocia in nulliparous women. Studying an exclusively nulliparous population is important since nulliparous women, in contrast to mutigravid ones, are especially predisposed to dystocia.[5,6] The purpose of this study is to assess the effects of epidural analgesia in labor on the incidence of cesarean section for dystocia in nulliparous women.

Material and methods

In the first 6 months of 1987, 711 consecutive nulliparous women with cephalic fetal presentations and singleton gestations were managed according to the principles of active management of labor.[5] Labor was diagnosed by regular, painful uterine contractions and cervical effacement and usually was accompanied by either bloody show or rupture of the membranes. Patients presenting with fetal distress were not included in this study. After the diagnosis of labor was established, amniotomy was performed. If 2 cm of cervical dilatation did not occur within 2 hours of amniotomy, oxytocin augmentation was initiated. Oxytocin was administered by controlled intravenous infusion (model

960, IMED Corp., San Diego) of 20 units diluted in 1 L of lactated Ringer's solution. Infusion was begun at 4 mU/min, was increased by 4 mU/min every 15 minutes, and did not exceed a maximum dose of 36 mU/min. If uterine activity exceeded a frequency of seven contractions in 15 minutes, the oxytocin infusion rate was not increased.

Patients were offered either narcotic agents or epidural analgesia if they requested assistance with pain relief during labor. Epidural analgesia was provided by an obstetric anesthesia department, with 24-hour in-house staffing. Each patient received an intravenous bolus infusion of 1000 ml of lactated Ringer's solution before induction of epidural analgesia. When the cervix was dilated to at least 3 cm, the patient was placed in the lateral decubitus or sitting position and an epidural catheter was placed via the L2-3 or L3-4 interspace and advanced 2 to 3 cm cephalad. Epidural analgesia was not routinely administered at 3 cm of cervical dilatation but was administered thereafter, on request by the patient. Initial bolus injection of bupivacaine 0.25% was then followed by a continuous infusion of 6 to 12 ml/hr of a 0.125% solution. Epidural infusions were adjusted to maintain a dermatomal level of T10-12. Continuous epidural infusion was continued in the second stage of labor as long as the patient achieved progress. Continuous electronic fetal monitoring was performed in all patients. Arterial and venous umbilical cord blood samples were obtained immediately after delivery and placed on ice. The samples for cord blood gas measurement were obtained by preheparinized 3 ml syringes (Marquest Medical products, Englewood, Colo.) to obtain a consistent concentration and preparation of heparin.

The following factors were compared in the epidural and nonepidural groups by means of χ^2 analysis or Student's t test as appropriate: maternal age, race, gestational age, cervical dilatation on admission, duration of labor, number of patients requiring oxytocin augmentation, duration of oxytocin use, maximum dose of oxytocin required, type of delivery, birth weight, frequency of 5-minute Apgar scores <7, and frequency of low umbilical cord pH values. The incidences of cesarean section for dystocia and for fetal distress were compared by χ^2 analysis by the Yates correction when appropriate. One-way analysis of variance and Scheffé test for groups with significant differences were used to compare the birth weights in the following four analgesia subgroups: those having no analgesia in labor, those having narcotic analgesia only, those having epidural analgesia only, and finally those having both epidural and narcotic analgesia.

For the purpose of definition in this study, cesarean sections for dystocia included those performed for arrest of the active phase in the first stage of labor, arrest of descent in the second stage of labor, i.e., fetus in persistent occipitoposterior position, minor deflexion or asynclitism, and cephalopelvic disproportion. Multivariate analysis was then performed with the linear logistic regression analysis technique,[7] and the following factors were controlled: maternal age, race, gestational age, cervical dilatation on admission, use of oxytocin, duration of oxytocin use, maximum infusion rate of oxytocin, total duration of labor, presence of meconium, and birth weight. There were six patients who received epidural analgesia after an established abnormal rate of dilatation (<1 cm/hr) and subsequently underwent cesarean section for dystocia. To address the selection bias even further, these six patients were deleted from the epidural group, and the incidence of cesarean section for dystocia was again compared in the epidural and nonepidural groups, both by χ^2 analysis and by multivariate analysis as described above. Data base and statistical analysis was assisted by computer software (Symphony, Lotus Development Corp., Cambridge, Mass.; Abstat, Anderson-Bell, Parker, Colo.; SPSS, SPSS Inc., Chicago).

Results

Of the 711 consecutive nulliparous women at term with spontaneous onset of labor, 142 (20%) received no analgesia in labor, 122 (17%) received narcotic analgesia only, 378 (53%) received epidural analgesia only, and 69 (10%) received epidural and narcotic analgesia. The epidural group consisted of 447 patients receiving only epidural or epidural combined with narcotic analgesia, and the nonepidural group consisted of 264 patients having either no analgesia or narcotic analgesia. The epidural and nonepidural groups are compared in Table I. Patients in the nonepidural and epidural groups had similar ages, gestational weeks, and racial background (45% black, 36% white, and 14% Hispanic).

Oxytocin augmentation was used in 397 (55.8%) of the 711 patients in this study. There was a significantly greater frequency ($p < 0.05$) of oxytocin augmentation in the epidural group (73%) than in the nonepidural group (27%). The duration of oxytocin use, maximum oxytocin dose, duration of labor, and birth weights were significantly greater ($p < 0.005$) in the epidural group than in the nonepidural group. Cesarean section for fetal distress occurred with similar frequency ($p > 0.20$) in both groups. The incidence of cesarean section for dystocia in the epidural group (10.3%) was significantly greater ($p < 0.005$) than that in the nonepidural group (3.8%). When macrosomic infants (≥4000 gm) were removed from the nonepidural and epidural groups, there remained a significant increase in incidence of cesarean section for dystocia in the nonepidural group (8 of 253 [3.2%] vs. 36 of 402 [9.0%], $p < 0.002$).

Multivariate analysis, controlling for the 10 factors listed above, demonstrated a significant increase in in-

Table I. Comparison of nonepidural and epidural groups

	Nonepidural group (n = 264)	*Epidural group (n = 447)*	*p Value**
Maternal age (yr)	23.1 ± 5.4	23.8 ± 5.4	NS
Gestation (wk)	39.5 ± 1.2	39.7 ± 1.2	NS
Cervical dilatation on admission (cm)	4.8 ± 2.6	3.0 ± 1.4	<0.05
Oxytocin augmentation	71 (27%)	326 (73%)	<0.05
Duration of oxytocin (hr)	3.1 ± 1.7	5.0 ± 3.0	<0.05
Maximum oxytocin (mU/min)	14.2 ± 8.4	17.9 ± 9.6	<0.05
Birth weight (gm)	3255 ± 456	3400 ± 466	<0.05
Total duration of labor (hr)	4.7 ± 2.8	8.6 ± 3.1	<0.05
Cesarean section for fetal distress	5 (1.9%)	9 (2.0%)	NS
Cesarean section for dystocia	10 (3.8%)	46 (10.3%)	<0.05†
	10 (3.8%)	40 (9.1%)	<0.05†
5 min Apgar score < 7	5 (1.9%)	2 (0.4%)	NS
Cord arterial pH	7.24 ± 0.07 (n = 233)	7.24 ± 0.07 (n = 414)	NS
Cord venous pH	7.32 ± 0.06 (n = 242)	7.32 ± 0.06 (n = 431)	NS
Cord arterial pH ≤ 7.15	17/233 (7.3%)	39/414 (9.4%)	NS
Cord venous pH ≤ 7.25	28/242 (11.6%)	39/431 (9.0%)	NS

Values represent a proportion or mean ± SD.

*Represents p value by Student's t, χ^2, or Fisher's exact test, as appropriate, and *NS* represents $p < 0.10$.

†p Value by linear logistic regression technique controlling for possible confounding variables. In the second comparison (3.8% vs. 9.1%) six patients were excluded because epidural analgesia was given after an abnormal labor pattern was established.

cidence ($p < 0.005$) of cesarean section for dystocia in the epidural group when compared with the nonepidural group. Six cases of cesarean section for dystocia were removed from the epidural group as the epidural anesthetic was placed during or after abnormal labor occurred. There remained a significant increase ($p < 0.005$) in incidence of cesarean section for dystocia in the epidural group (9.1%) when compared with the nonepidural group (3.8%) by multivariate analysis controlling the same factors.

Meconium-stained amniotic fluid during labor occurred in similar frequency ($p > 0.20$) in the nonepidural (20%) and epidural (23%) groups. The cord arterial pH value (mean ± SD) in the nonepidural group (7.24 ± 0.07; $n = 232$) was similar to that of the epidural group (7.24 ± 0.07; $n = 414$). Likewise, the cord venous pH value (mean ± SD) in the nonepidural group (7.32 ± 0.06; $n = 241$) was similar to that of the epidural group (7.32 ± 0.06; $n = 431$). All of the other cord arterial and venous blood gas parameters including P_{CO_2}, P_{O_2}, bicarbonate, and base deficit were also similar in both the nonepidural and epidural groups. Both the nonepidural and epidural groups had similar proportions of 5-minute Apgar scores <7, cord arterial pH values ≤7.15, and cord venous pH values ≤7.25 (Table I).

These four analgesia subgroups were studied separately: patients having no analgesia, patients having narcotic analgesia, patients having epidural analgesia, and finally patients having both epidural and narcotic analgesia (Table II). Comparison of the birth weights in the four analgesia subgroups by analysis of variance resulted in an F test of 5.80 ($p = 0.0006$). Scheffé test demonstrated a significant difference between patients receiving narcotics only and those with epidural analgesia only ($p = 0.02$) and between those receiving narcotics only and those receiving epidural analgesia and narcotics ($p = 0.03$). There was no significant difference in birth weight between those patients receiving no analgesia versus those receiving only epidural analgesia, yet there was a significant increase in cesarean section for dystocia in the latter group (3.5% vs. 10.3%, $p < 0.01$). The incidence of cesarean section for dystocia in the various subgroups with and without macrosomic newborns (≥4000 gm) is depicted in Table II.

Comment

The incidence of cesarean section for dystocia in the epidural group was significantly greater than that in the nonepidural group, despite correction for selection bias and controlling for confounding variables by multivariate analysis. This study suggests that epidural analgesia in labor may increase the risk of cesarean section for dystocia in nulliparous women. This finding is especially significant in our institution since oxytocin is used aggressively in a large proportion of our nulliparous women (55.8% in this study) according to the principles of active management of labor.[5] Active management of labor was introduced to our institution in 1985 and significantly ($p < 0.05$) reduced the total cesarean section rate from 25% to 20%, without altering major perinatal outcome variables.[6] This decrease in the total cesarean section rate was entirely due to the

Table II. Comparison of the analgesia subgroups

	No analgesia	*Narcotic analgesia*	*Epidural analgesia*	*Epidural and narcotic analgesia*
Cesarean section for dystocia*	3.5% (5/142)	4.1% (5/122)	10.3% (39/378)	10.1% (7/69)
Cesarean section for dystocia,† birth weight < 4000 gm	3.0% (4/135)	2.6% (3/117)	9.4% (32/342)	6.7% (4/60)
Birth weight‡ (gm)	3272 ± 450	3237 ± 464	3392 ± 465	3448 ± 472

All values are expressed as proportions or mean ± SD.

*A χ^2 analysis demonstrates a significant difference between the following subgroups: no analgesia versus epidural; no analgesia versus epidural and narcotic; narcotic versus epidural; narcotic versus epidural and narcotic ($p < 0.05$).

†A χ^2 analysis demonstrates a significant difference between the following subgroups: no analgesia versus epidural narcotic versus epidural ($p < 0.05$).

‡Analysis of variance and Scheffé test show a significant difference in birth weight between the following subgroups: narcotic versus epidural ($p = 0.03$); narcotic versus epidural and narcotic ($p = 0.02$). No difference in birth weight was noted between the no analgesia versus the epidural subgroups, yet there was significant increase in cesarean section for dystocia between these subgroups ($p < 0.01$).

decrease in incidence of cesarean section for dystocia in nulliparous women from 15% to 10% ($p < 0.05$). However, the implementation of active management of labor in our institution was only partially successful, as it did not decrease the incidence of cesarean section to the 5% range as it has remained at the National Maternity Hospital in Dublin.[5] There have been many possible explanations for our "partial success." One argument considers the fact that the Dublin population remains essentially homogeneous, in contrast to our multiracial population. However, Turner et al.[8] in England have recently introduced active management of labor in a multiracial population and achieved cesarean section rates approaching those in Dublin.[5] Another argument suggests that lack of adherence to the strict principles of active management of labor may be responsible for the "partial success" in Houston. However, Akoury et al.[9] also achieved cesarean section rates approaching those in Dublin, without the benefit of an "experienced Irish hand," such as we had in Houston (P. C. B.). Approximately 63% of our parturient women received epidural analgesic for labor, in contrast to only 5% in Dublin,[5] 25% in the study of Akoury et al.,[9] and 31% in the study of Turner et al.[8] These observations are consistent with the findings of this study; i.e., epidural analgesia in labor may increase the incidence of cesarean section for dystocia.

There are many mechanisms by which epidural analgesia could increase the incidence of cesarean section for dystocia. A decrease in uterine activity[10, 11] without appropriate intervention with oxytocin could result in more cesarean sections for dystocia. The allegation that oxytocin causes birth asphyxia and other adverse perinatal outcomes is one of the more common medicolegal claims in obstetrics in the United States.[12] Therefore, despite recent data demonstrating the safety of oxytocin,[13] it is often inappropriately withheld because of medicolegal concerns. Relaxation of the pelvic diaphragm could predispose fetuses in a cephalic presentation to minor malpresentations such as occipitoposterior, deflexion, and asynclitism.[10, 14, 15] In addition, epidural analgesia could decrease the maternal stimulus and ability to push during the second stage.[10, 15] Several studies[14] have associated epidural analgesia with increased rates of instrument-assisted vaginal delivery. In the current medicolegal climate, the obstetrician is less likely to intervene with forceps, and therefore an increased incidence of cesarean section for dystocia could result.

The popular belief that epidural analgesia does not increase the incidence of cesarean section is not clearly established in the literature. In fact, Diro and Beydoun[1] found that epidural analgesia was associated with an increased incidence of cesarean section. In their study the authors[1] retrospectively compared 43 parturient women of mixed parity receiving epidural analgesia with 43 matched control women and found a significant increase in the incidence of cesarean section for dystocia in the epidural group. One retrospective analysis[2] suggested that epidural analgesia has no effect on the incidence of cesarean section during a 10-year interval in which the incidence of epidural use rose from 0% to 40%. However, it is not clear how this conclusion was made since the incidence of cesarean section rose from 6.48% to 11.03% during the same time period. McNeill and Wilson[16] noted no increase in total cesarean section rate in 500 consecutive patients receiving epidural analgesia in labor when compared with the total obstetric population. However, their study[16] did not assess the incidence of cesarean section for dystocia and did not investigate an exclusively nulliparous population. Several observational studies reported cesarean section rates in large series of patients with epidural analgesia; however, no comparisons with control groups were made.[17-19] In a controlled study Studd et al.[20] found no effect of epidural analgesia on the

incidence of emergency cesarean section for fetal distress; however, they did not report the incidence of cesarean section for dystocia. Our results are consistent with these findings, demonstrating no effect of epidural analgesia on the incidence of cesarean section for fetal distress.

More recently, two randomized, double-blind, placebo-controlled studies[3, 4] suggested that epidural analgesia, via continuous infusion after 8 cm of dilatation and throughout the second stage, did not increase the incidence of cesarean section. However, both experimental and control groups received epidural anesthetic up to 8 cm of cervical dilatation and then were randomized to continuous infusion of placebo or local anesthetic agent. Therefore these studies[3, 4] assessed the effect of continuous-infusion epidural anesthesia in late labor, not the effect of standard epidural analgesia begun early in active labor. To our knowledge, the present study is the only controlled study specifically analyzing the effect of epidural analgesia on the incidence of cesarean section for dystocia in nulliparous women in labor. If epidural analgesia increases cesarean sections for dystocia in our institution, where active management of labor policies dictate an early aggressive treatment of dysfunctional labor, a much more profound effect would be anticipated in other hospitals.

We recognize potential criticisms of our study, the most significant of which is the selection bias in comparing the nonepidural group with the epidural group. Clearly, some patients who do not initially request epidural analgesia will begin to labor abnormally and then will either request or be advised to have epidural analgesia. As Table I suggests, the nonepidural and epidural groups are different, as evidenced by the somewhat larger birth weights and lesser cervical dilatation on admission in the epidural group. We attempted to address this concern by eliminating from the study all of the patients who had cesarean section for dystocia in the epidural group who received epidural analgesia after abnormal labor was established. Furthermore, we controlled for the significant confounding variables by multivariate analysis. This method of analysis would tend to nullify the difference in cesarean section rates for dystocia between the epidural and nonepidural groups if the cause was related to the confounding variables analyzed. However, there remained a significant difference between the two groups.

One could attempt to explain the difference in cesarean sections for dystocia in the nonepidural and epidural groups by the slightly larger birth weights and higher risk status of the patients in the epidural group. However, analysis of variance and Scheffé test demonstrated no difference in birth weights between those patients having no analgesia and those having only epidural analgesia, yet there was a significant increase in cesarean section for dystocia when these subgroups were compared (Table II). When all the macrosomic newborns were deleted, there also remained significant increases in cesarean section for dystocia in the epidural group. Finally, the outcome data do not support the contention that the epidural group was a significantly higher risk group. Both groups had similar frequencies of cesarean section for fetal distress, similar cord arterial and venous pH values, and similar proportions of low 5-minute Apgar scores and low cord pH values (Table I).

For the reasons listed above, we do not think that the discrepancy in cesarean sections for dystocia between the groups (Table I) or subgroups (Table II) can be fully explained by selection bias. Unless patients are randomly assigned to a nonepidural group before labor, an ideal control group would be impossible to achieve. Ethical considerations and patient drop out will be problems with randomly allocating patients to a nonepidural group before labor.[15] Therefore prospective studies are not the final solution and, unless patients are randomized before the onset of labor, there will also be problems with selection bias. Further study of nulliparous women at term with spontaneous onset of labor, controlling for labor abnormalities and time of epidural placement, is necessary to confirm our findings and prove a cause-effect relationship. If a cause-effect relationship is established, further study to ascertain subgroups of nulliparous women who are at high risk of developing dystocia with epidural analgesia would be clinically useful.

We thank Mr. Kenneth E. Thorp, Sr., for assistance with the data base, and the Obstetrical Anesthesia Department at the University of Texas Medical School–Houston/Hermann Hospital for providing their excellent services.

Can platelet volume predict progressive hypertensive disease in pregnancy?

James J. Walker, MB, ChB,[a] Alan D. Cameron, MB, ChB,[a] Steingrimur Bjornsson, MD,[a] Charles R. J. Singer, MB, ChB,[b] and Carol Fraser, FMILS[b]

Glasgow, Scotland

Increase in platelet size has been found in conditions with increased platelet destruction and use. This increase in platelet size can be found in patients with moderate or severe hypertension in pregnancy, even in the presence of a normal platelet count. The goal of this study was to investigate whether an increase in platelet size was present before the manifestation of the disease and therefore could be used to predict the progression of the disease before it is clinically apparent. Three hundred normal primigravid pregnancies were studied between 28 and 30 weeks' gestation, and blood was taken to assess platelet count and mean platelet volume. Two hundred sixteen patients had no hypertensive problems during their pregnancy, 84 developed hypertension, 62 had mild hypertension only with diastolic blood pressures between 90 and 99 mm Hg, 13 had moderate hypertension with diastolic blood pressures between 100 and 109, and nine had severe hypertension with diastolic blood pressure above 110. No difference was found between these groups in the parameters measured. Therefore it was felt that platelet volume may not be a useful screening test in a low-risk population. A second study was carried out to investigate the serial changes in these parameters in patients at risk of progressive disease. Thirty-four patients with essential hypertension were followed from 24 weeks with serial blood sampling to study changes in platelet size. An additional 40 patients with mild pregnancy-induced hypertension were also studied. From these patient groups, 20 patients developed severe hypertension. The mean platelet volume increased significantly at least 1 week before the hypertension became clinically apparent. There was no change in platelet count at this time. It is concluded that increasing platelet size can predict which patients are likely to progress to severe disease before it becomes clinically obvious. (AM J OBSTET GYNECOL 1989;161:676-9.)

Key words: Platelets, platelet volume, pregnancy-induced hypertension

In pregnancy-induced hypertension and preeclampsia, studies have shown changes in platelet numbers, platelet survival, and mean platelet volume, which have been interpreted as evidence of increased platelet consumption.[1-5] Some studies have suggested that platelet count falls early in the disease and precede hypertensive renal changes, suggesting that platelet consumption plays an active role in the pathophysiology of this disorder.[3] We have previously shown that an increase in platelet size was found in patients with moderate or severe hypertension in pregnancy, even in the presence of a normal platelet count.[5] Increased mean platelet volume is further evidence of increased platelet turnover in patients with preeclampsia. However, since a decrease in platelet count is not inevitable even at the onset of an eclamptic episode,[6] it may be possible to show increasing platelet consumption in these patients by demonstrating an increase in platelet size, even though platelet count remains within the normal range. Also, since Redman et al.[3] suggest that the fall in platelet count occurs before the rise in serum urate, a change in mean platelet volume occurring before a fall in platelet count may predict the progression of preeclampsia before it is clinically apparent.

Methods

Patients. This study was conducted in two parts. In the first part 300 normotensive primigravid patients were studied between 28 and 30 weeks of gestation. Blood was taken to assess hematocrit level, platelet count, and mean platelet volume. The results obtained from these patients were compared with the outcome of their pregnancies. In the second part 34 patients with essential hypertension were followed from 24 weeks. A diagnosis of essential hypertension had been made in these patients either before pregnancy or before 20 weeks' gestation in this pregnancy. The group was made up of 26 parous women and eight primigravidas. No patient received any antihypertensive therapy. An additional 40 primigravid patients who had mild pregnancy-induced hypertension at between 28

Table II. Outcome of 34 patients with essential hypertension sampled serially and changes in mean platelet volume; total numbers for each group are reduced as gestation increases as patients are delivered

Outcome	*No.*	*24 wk*	*28 wk*	*32 wk*	*36 wk*	*Significance (1)**
Stable	20	8.5 ± 1.2	8.6 ± 1.0	8.8 ± 1.4	8.7 ± 1.1	NS
Moderate	8	8.7 ± 1.0	8.7 ± 1.1	8.9 ± 1.3	9.1 ± 1.3	$p < 0.01$
Severe	6	8.6 ± 1.2	9.1 ± 1.4	9.7 ± 1.2	10.2 ± 1.2	$p < 0.005$
Significance (2)†		NS	NS	$p < 0.01$	$p < 0.005$	

*Significance (1): Significance within groups is calculated from the 24-week mean platelet volume against the 36-week value or the last value before delivery if the patient was delivered before 36 weeks. Significance test used was the Wilcoxon signed-rank test for matched pairs.

†Significance (2): Significance between groups was calculated between the severe and stable groups using patients in each group who were undelivered at the gestation stated. Significance test used was the Mann Whitney U test.

and 34 weeks' gestation were also studied from the time the condition was first diagnosed. Both of these groups attended our outpatient day-care monitoring unit on a weekly basis unless admission was required. Serial sampling was carried out weekly in both groups for hematocrit, platelet count, and platelet size. Sampling continued on a weekly basis until delivery. All patients were managed by the hospital hypertension team and routine monitoring followed the protocol for the hospital, which consists of weekly blood pressure monitoring, uric acid estimation, platelet count, urinalysis for protein, nonstress test and ultrasound assessment for fetal weight, and liquor volume. Platelet size data were unavailable to management, and all analysis for this study was carried out after the pregnancy was over.

The protocol for this study was submitted to and passed by our local hospital Ethical Committee.

Mild pregnancy-induced hypertension was diagnosed if blood pressure remained between 90 and 99 mm Hg, moderate if diastolic blood pressure was persistently between 100 and 109 mm Hg, and severe if above 110 mm Hg. For purposes of this study, no other parameters, such as proteinuria or uric acid, were used in the criteria for diagnosis.

Sample handling. Blood samples were obtained from a large vein with a syringe and 19-gauge needle but no tourniquet. Blood was immediately mixed with dipotassium ethylenediaminetetraacetic acid (1.5 mg/ml blood) and maintained at room temperature for 90 to 120 minutes before analysis. Analysis was carried out on a Coulter Counter (Model S-Plus, Coulter Electronics Ltd., Luton, United Kingdom), which was subject to continous quality control. Channel calibration with latex particles (platelet volume calibration latex, Model No. 8.6 fl; Coulter Electronics) was carried daily and later weekly to ensure sample comparability with respect to mean platelet volume and platelet destribution width values generated.

Statistics. Fisher's test, Mann-Whitney U test, and the Wilcoxon signed-rank test for matched pairs were used for statistical analysis in this study.

Results

Of the 300 normal primigravid pregnancies, 216 patients had no hypertensive problems throughout the rest of their pregnancy, and 84 developed hypertension. Although a trend upward could be seen, when all parameters for these patients were compared, there was no significant difference in any of the parameters measured (Table I). Therefore it was felt that platelet volume at 28 to 30 weeks' gestation could not be used as a screening test in this low-risk population. If the mean platelet volume of this group was split into those who had a value above the mean and those who had a value below the mean, it was found that eight of the 154 patients who had a mean platelet volume >8.5 went on to develop severe preeclampsia, whereas only one of the 146 patients with and a mean platelet volume of <8.5 developed severe preeclampsia. Although this was statistically significant ($p < 0.02$), it is of little clinical significance, with a positive predictive value of only 5.19%.

Table III. Outcome of 40 patients with mild pregnancy-induced hypertension sampled serially and changes in mean platelet volume; timing is related to when the diagnosis was made and the first 3 weeks afterward and not to gestation; total numbers for each group are reduced as the weeks increase

Outcome	*No.*	*At diagnosis*	*1 wk*	*2 wk*	*3 wk*	*Significance (1)**

Moderate	14	8.8 ± 1.2	9.0 ± 1.2	9.1 ± 1.4	9.2 ± 1.2	NS
Severe	9	8.8 ± 1.3	9.1 ± 1.4	10.0 ± 1.2	11.2 ± 1.2	$p < 0.001$
Significance (2)†		NS	NS	$p < 0.005$	$p < 0.001$	

*Significance (1): Significance within each group was calculated from the mean platelet volume at diagnosis of the mild hypertension compared with the 3-week mean platelet volume or the last mean platelet volume before delivery if patients were delivered before this time; significance test used was the Wilcoxon signed-rank test for matched pairs.

†Significance (2): Significance between groups was calculated between the severe and stable groups at the times indicated using the patients still undelivered at that time in both groups; significance test used was the Mann Whitney U test.

In the serial study of 34 patients with essential hypertension, 14 patients had worsening hypertension (Table II). There was no significant change in the mean platelet volume in the 20 patients who remained stable. A small but significant increase was found in those patients who progressed to moderate disease ($p < 0.01$), and a large increase occurred in those who developed severe hypertension ($p < 0.005$). Between-group differences were seen only between the stable group and the severely affected group between 32 and 36 weeks' gestation. The largest rise in mean platelet volume seen in the stable group was 0.6 fl. If a rise of 1 fl was taken as significant, all patients developing severe disease had a rise >1 fl at least 1 week before a diagnosis of severe hypertension was made by the hypertension team. Onset of severe disease ranged from 32 to 38 weeks. Table II gives values up to 36 weeks, since after this time a significant number of patients in each group had been delivered, and mean values for the groups would be less valid. Similar results were seen for the 40 primigravid patients with mild pregnancy-induced hypertension followed serially (Table III). No change was seen in the mean platelet volume in the patients who remained mildly hypertensive or those who progressed to moderate hypertension, but a significant rise was found in those patients who developed severe disease. Similarly, only the severe group had a rise in mean platelet volume compared with the stable group. All patients with severe hypertension had a rise of >1 fl in mean platelet volume. This rise was seen in this group at least 1 week before a clinical diagnosis of pregnancy-induced hypertension was made by the hypertension team. The development of severe hypertension was between 2 and 4 weeks after the diagnosis of mild disease. Gestational age at the time of diagnosis ranged between 30 and 36 weeks. In 15 patients from both groups who developed severe disease with a rise of 1 fl in the mean platelet volume, seven of the 15 babies were born with a birth-weight under the tenth percentile compared with only 12 of 59 babies born to mothers who remained either stable or progressed only to moderate pregnancy-induced hypertension.

Comment

Hypertension in pregnancy is a very common diagnosis. The vast majority of patients remain in the mild-to-moderate group and do not have any major obstetric problem, and the outcome is good for both mother and baby. However, in a small group of patients, the disease can progress to a more severe form, increasing the maternal risk of seizure and cerebrovascular accident, along with increasing morbidity of severe hypertension and the required medication and hospitalization. For the baby, severe hypertension is associated with increased placental insufficiency and intrauterine growth retardation. Many studies in women with pregnancy-induced hypertension and preeclampsia have shown changes in platelet numbers,[1-3,5] platelet survival,[4,7] and mean platelet volume,[4,5] which have been interpreted as increased consumption. Thrombocytopenia is a common finding and is associated with progressive disease and also disease severity. Platelet lifespan is known to be reduced in pregnancy-induced hypertension and is thought to be caused by intravascular platelet aggregation and increased adhesion to vascular endothelium.[7] Because the signs of this platelet consumption appear to antedate other signs and clinical manifestations of the disease, many investigators believe that platelets are involved in the pathophysiology of this disorder.[3] This is the reasoning behind the low-dose aspirin studies that are now being undertaken in the United States and the United Kingdom. Although the findings of this study were not evidence of a significant increase in platelet consumption remote from the onset of the clinical disease, the fact that mean platelet volume tended to be higher in patients who progressed suggests that there may be early platelet consumption in this group. However, it is of no value as a screening test. Similarly, there was no evidence that an increased hematocrit level was associated with patients who devel-

oped serious hypertension as previously suggested. The second part of the study confirmed that there was increasing platelet consumption in patients who developed moderate and severe pregnancy-induced hypertension and that the changes related to this increased platelet consumption antedated the appearance of clinical signs by at least 1 week. Since other methods of investigation can be used to help monitor patients at risk of developing progressive pregnancy-induced hypertension, it is difficult to know whether mean platelet volume is necessarily any better than monitoring serial platelet counts and uric acid levels. Correlation of apparent intrauterine growth retardation with patients who developed severe disease with rising mean platelet volume may support the evidence that patients with severe disease have increasing platelet consumption and deposition of platelets and fibrin.[8] Such changes within the placenta could partly explain the findings described in previous pathologic studies.[9] These findings support the argument for the use of low-dose aspirin in patients believed to be at risk of severe preeclampsia or intrauterine growth retardation. If this reduces the rate of platelet consumption that occurs, it may well slow or stop progression of the disease to its severe form and reduce the chance of placental insufficiency. A large-scale study of patients at risk with rising mean platelet volume as a marker for intervention may be indicated.

Measurement of cardiac output in pregnancy by thoracic electrical bioimpedance and thermodilution

A preliminary report

Damon I. Masaki, MD, Jeffrey S. Greenspoon, MD, and Joseph G. Ouzounian, BS
Los Angeles, California

Thoracic electrical bioimpedance is a noninvasive, continuous method of obtaining cardiac output that requires no operator skill. However, the most recent thoracic electrical bioimpedance technology has not been validated in pregnancy. We therefore compared two methods of measuring cardiac output in pregnancy, thoracic electrical bioimpedance and thermodilution. We studied 11 patients who required pulmonary artery catheterization for peripartum management and measured cardiac output simultaneously by thoracic electrical bioimpedance and thermodilution. Among eight of nine patients, there was agreement (within ±20%) between the two methods. Bivariate linear regression with these nine cases showed excellent correlation ($r = 0.91$, $p < 0.001$) with a slope of 1.04, which indicated a one-to-one relationship between thoracic electrical bioimpedance and thermodilution. The remaining two cases were removed from analysis because of septic shock in one case (which invalidates thoracic electrical bioimpedance) and 4+ tricuspid regurgitation in another case (which invalidates thermodilution). These data support that thoracic electrical bioimpedance measurement of cardiac output may be valid in most peripartum patients. (AM J OBSTET GYNECOL 1989;161:680-4.)

Key words: Pregnancy, cardiac output, thoracic electrical bioimpedance

The estimation of cardiac output is an integral part of the management of pregnant women who have underlying cardiovascular disorders or who develop serious medical complications. The most commonly employed clinical method of measuring cardiac output is thermodilution, which requires the insertion of a pulmonary artery catheter. The invasive nature precludes the use of thermodilution to assess cardiac output in the majority of patients. Although thermodilution to assess cardiac output has gained wide acceptance and is considered the "gold standard" in clinical settings, it has an overall error of 15% to 20%[1] and overestimates cardiac output in low-flow states.[2] A noninvasive alternative to thermodilution that provides continuous updating of cardiac output is desirable.

Measurement of cardiac output by Doppler techniques is noninvasive and has been validated in pregnancy.[3, 4] However, these methods require significant technical skill and are intermittent rather than continuous.

Thoracic electrical bioimpedance, also referred to as impedance cardiography, is a noninvasive method of estimating stroke volume and, therefore cardiac output. In addition, thoracic electrical bioimpedance provides continuous beat-to-beat data on cardiac output and requires no technical skill provided the electrodes are correctly placed. Earlier studies of cardiac output by thoracic electrical bioimpedance during pregnancy have been reported with older thoracic electrical bioimpedance technology.[5-7] The early studies used cumbersome tetrapolar band electrodes and were based on the Kubicek equation, which had a tendency to overestimate cardiac output.[8] Recent improvements in measurements of cardiac output by thoracic electrical bioimpedance involved the modification of the Kubicek equation by Sramek and Bernstein,[9] and incorporation of the calculations into a computer microprocessor called the Noninvasive Continuous Cardiac Output Monitor, model 3 (NCCOM-3). Studies with the NCCOM-3 system indicate that measurement of cardiac output by thoracic electrical bioimpedance is reliable in nonpregnant adults[10-12] and pediatric patients[13] but has not been validated in pregnancy.

The NCCOM-3 system has been revised several times.[14] The revision 4 model (available in 1985) was unreliable when the heart rate exceeded 150 beats/min. The studies previously cited used the revision 4 system.[10-13] Our study used revision 6 of the NCCOM-3, which has been available since 1986. Revision 6 was modified to permit measurement of cardiac output at heart rates up to 199 beats/min, and adjusted the Sramek stroke volume equation for weight.[14]

ARDS, Adult respiratory distress syndrome; *PIH*, pregnancy-induced hypertension; *MS*, mitral stenosis; *TR*, tricuspid regurgitation; *MR*, mitral regurgitation.

Difference (%) = Thoracic electrical bioimpedance − Thermodilution/Thermodilution × 100.

Cardiac output reported is mean and range of five measurements expressed in liters per minute.

*Patient 10 not included in agreement or regression analysis because thermodilution is not reliable in measuring cardiac output in patients with 4+ tricuspid regurgitation.

†Patient 11 not included in the agreement or regression analysis because the estimation of cardiac output by thoracic electrical bioimpedance has not been reliable in septic shock.

We present the first study of peripartum patients undergoing pulmonary artery catheterization in whom simultaneous thermodilution to assess cardiac output and measurement of cardiac output by thoracic electrical bioimpedance, using revision 6 of the NCCOM-3 model, were performed to compare the two methods.

Material and methods

Eleven peripartum patients were studied at the Los Angeles County–University of Southern California Medical Center during a 15-month period from November 1987 to January 1989. Patients were included if they required pulmonary artery catheterization for peripartum management and consented to thoracic electrical bioimpedance.

The pulmonary artery catheters (model 93A-831-7.5F, American Edwards Laboratories, Irvine, Calif.) were inserted percutaneously via the right internal jugular vein in all cases. The medical conditions requiring pulmonary artery catheterization are shown in Table I. The correct position of the pulmonary artery catheter was confirmed by pressure waveform and chest radiograph. Pressure transducers (model T12AD-R, Gould Inc., Oxnard, Calif.) were calibrated to a zero reference at the midaxillary line. All measurements were made with the patient in the supine position with a left lateral tilt of approximately 25 degrees. A 10 ml injectate of 5% dextrose in water at room temperature (23° to 25° C) was used for obtaining thermodilution to assess cardiac output. Five consecutive thermodilution measurements were made randomly with respect to the respiratory cycle, regardless of whether the patient had spontaneous respirations or required mechanical ventilation; the five readings were then averaged. Values obtained by thermodilution to assess cardiac output were determined on a cardiac output computer (model 9520A, American Edwards Laboratories).

Determination of cardiac output by thoracic electrical bioimpedance was obtained with the NCCOM-3, revision 6 (NCCOM-3, rev. 6, Bomed Medical Manufacturing Ltd., Irvine, Calif.). Eight electrodes (Silvon ECG electrodes, NDM Corp., Dayton, Ohio) were applied as follows (see Fig. 1). Two sensing electrodes were placed 180 degrees apart from each other at the root of the neck, and two sensing electrodes were placed 180 degrees from each other at the level of the xiphoid

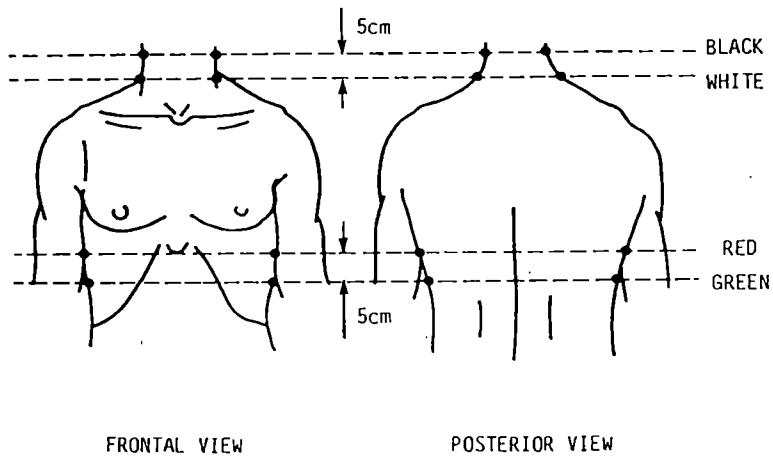

Fig. 1. Diagram of electrode placement. Electrodes are color coded to ensure correct application. *Black* and *white* (root of neck) electrodes are 180 degrees apart. *Red* (level of xiphoid) and *green* electrodes are at midaxillary line. Black and green electrodes are transmitting electrodes; white and red ones are sensing electrodes. (From Bomed Manufacturing Ltd.)

process at the midaxillary line. Two pairs of transmitting electrodes were placed adjacent to the sensing electrodes in the same plane so that the electrode centers were 5 cm apart. The cardiac output by thoracic electrical bioimpedance for each heartbeat for the next 12-beat interval (which is the usual interval required for a cardiac output measurement determined by thermodilution) is averaged by the microprocessor in the NCCOM-3, rev. 6, and displayed.

At the beginning of the five measurements of cardiac output by thermodilution, a cardiac output by thoracic electrical bioimpedance reading was begun simultaneously. A total of five simultaneous measurements were performed on each patient and averaged.

Statistical analysis to assess agreement between the measurement of cardiac output by thermodilution and thoracic electrical bioimpedance was performed as described by Bland and Altman.[15] Thermodilution to assess cardiac output and cardiac output by thoracic electrical bioimpedance data were also analyzed by bivariate linear regression with MR-TOD (Medical Research–Time Oriented Database, Retriever Data Systems, Seattle, Wash.).

Patients gave written informed consent before pulmonary artery catheterization for medical management and before cardiac output by thoracic electrical bioimpedance studies. The use of thoracic electrical bioimpedance to determine cardiac output was approved by the Human Research Review Committee at the University of Southern California–Los Angeles County Medical Center.

Results

Data obtained from the individual patients are shown in Table I. The percent difference between the two methods is also calculated. Two patients were excluded from the analysis for agreement and bivariate linear regression because both had a condition in which cardiac output estimation is inaccurate with one of the methods. Patient No. 10 had tricuspid regurgitation (4+), rendering thermodilution assessment of cardiac output invalid. Patient 11 had septic shock, a condition in which determination of cardiac output by thoracic electrical bioimpedance has been unreliable in nonpregnant patients.

The cardiac output data for nine patients are presented graphically as recommended by Bland and Altman[15] in Fig. 2. Bivariate linear regression analysis between thermodilution to assess cardiac output and cardiac output by thoracic electrical bioimpedance, in which thermodilution to assess cardiac output was designated as the independent variable was also performed. The results of this analysis are: Cardiac output by thoracic electrical bioimpedance $= -1.03 \pm 1.04 \times$ (Cardiac output by thermodilution); $r = 0.91$ ($p < 0.001$). The standard error of estimate was equal to 1.07.

Comment

Thoracic electrical bioimpedance is a noninvasive blood flow technology that estimates left ventricular stroke volume on a continuous beat-to-beat basis. With each ventricular contraction, there is an increase in the electrical conductance of the thoracic cavity and results in the bioimpedance waveform. The NCCOM-3 computer microprocessor senses and records these impedance changes through its eight-lead montage and uses them to calculate stroke volume and thus cardiac output. The Sramek-Bernstein equation used to calculate stroke volume (SV) is:

$$SV = L^3/4.2 \times T_{LVE} \times (dz/dt)_{max}/Z_0$$

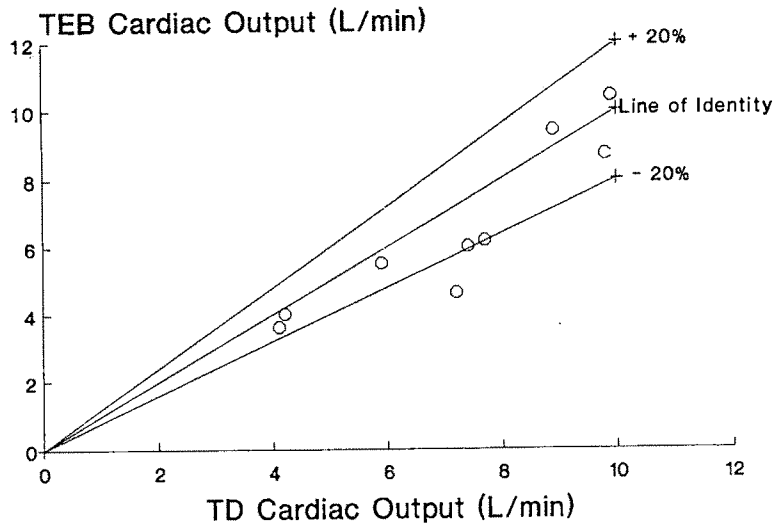

Fig. 2. Cardiac output by thoracic electrical bioimpedance for the first nine patients described in Table I. *Line of identity* designates perfect agreement between the two methods. The lines for ±20% of cardiac output indicate accepted accuracy limits in measurement of cardiac output.[1]

The derivation of this equation was reviewed by Bernstein.[9] In the equation, T_{LVE} is left ventricular ejection time (in seconds, displayed as ventricular ejection time), $(dZ/dt)_{max}$ is the maximum rate of impedance change (in ohms per second, displayed as ejection velocity index), and Z_0 is the basal thoracic impedance (in ohms, displayed as the thoracic fluid index). The L value is the thoracic length, which is used to calculate the thoracic volume. Note that the L value is the only value not determined by the NCCOM-3 directly from the bioimpedance waveform. The accuracy of the L value is critical because it appears in the third power in the stroke volume equation. An error of 1 cm in this value can alter the cardiac output by as much as 10%.[9] The L value is derived from a nomogram that uses the patient's height and weight and adjusts for deviations from ideal body weight. This nomogram was derived from nonpregnant subjects. Although cardiac output by thoracic electrical bioimpedance estimates by the NCCOM-3 are reliable in most nonpregnant adults, the cardiac output by thoracic electrical bioimpedance method has not been validated in pregnancy.

The cardiac output by thoracic electrical bioimpedance estimate was less than thermodilution to assess cardiac output by 35.6% in patient No. 9. One possible explanation for this discrepancy between the method is that the L value for short subjects may be incorrect. A study of cardiac output by thoracic electrical bioimpedance in short (pediatric) patients suggested that the L value is underestimated with respect to height in short (pediatric) patients, therefore cardiac output is underestimated by thoracic electrical bioimpedance.[13] This patient's height was 144 cm (4 feet 9 inches), which is near the lower limit (145 cm) of the nomogram for the determination of L. These potential errors in L may account for the observed differences in cardiac output.

Previous studies in nonpregnant adults demonstrated that cardiac output by thoracic electrical bioimpedance consistently underestimates cardiac output measured by thermodilution and is unreliable during sepsis with high cardiac output.[8] This is probably caused by augmented blood flow to the skin from intense peripheral vasodilation. The thorax thus behaves more like a "shell conductor than a volume conductor."[8] The $(dZ/dt)_{max}$ and ultimately cardiac output by thoracic electrical bioimpedance are therefore underestimated during this condition. The cardiac output by thoracic electrical bioimpedance underestimated cardiac output by thermodilution by 32.4% in patient no. 11 (during septic shock), which confirms this observation. This patient was excluded a priori from the analysis comparing the two methods because she had a clinical condition in which measurement of cardiac output by thoracic electrical bioimpedance is known to be invalid. Whether the vasodilator properties of drugs such as hydralazine and magnesium sulfate have an effect on the cardiac output by thoracic electrical bioimpedance similar to that of sepsis was not studied. This possibility should be considered in patients with pregnancy-induced hypertension (patients no. 5 to 9). All five of these patients received hydralazine and magnesium sulfate at the time of this study. Complex dysrhythmias, electrocautery, and motion artifact may interfere with cardiac output by thoracic electrical bioimpedance estimates[8] but were not encountered in this series.

The comparison of thermodilution to assess cardiac output and cardiac output by thoracic electrical bio-

impedance requires that both methods be done with accuracy in addition to proper statistical analysis. The use of thermodilution to assess cardiac output measures right ventricular cardiac output at the point where the thermistor on the tip of the pulmonary artery catheter is located. Thermodilution to assess cardiac output is sensitive to changes in preload and can vary up to 50% during different phases of ventilation.[16] Thermodilution to assess cardiac output performed exclusively at end-exhalation will be more reproducible, which is useful for determining trends in the clinical setting but will be less accurate in terms of representing cardiac output during the entire respiratory cycle.[17] We therefore chose to perform thermodilution to assess cardiac output randomly in relation to the respiratory cycle. The volume (10 ml) and temperature (23° to 25° C) of the injectate selected simplifies the technique without loss of accuracy.[18] Accurate measurement of cardiac output by thoracic electrical bioimpedance requires careful determination of the thoracic length and correct electrode placement.

The statistical comparison of thermodilution to assess cardiac output with assessment of cardiac output by thoracic electrical bioimpedance was performed only after all five cardiac output values by each method were averaged. The large effect of ventilation on thermodilution to assess cardiac output variability and the lack of effect on cardiac output by thoracic electrical bioimpedance would make comparisons between single thermodilution to assess cardiac output and cardiac output by thoracic electrical bioimpedance estimates misleading. Fig. 2 graphically displays the comparison between thermodilution to assess cardiac output and assessment of cardiac output by thoracic electrical bioimpedance. If perfect agreement existed between the two methods of measuring cardiac output, then all points would fall on the line of identity. The ±20% cardiac output lines on Fig. 2 show the accepted accuracy limits of thermodilution to assess cardiac output.[1] The estimate of cardiac output by thoracic electrical bioimpedance is within the ±20% limits in eight of nine cases.

Regression analysis also was performed, which requires that each data point be comprised of independent observations. Therefore one observation from each patient was analyzed for correlation. An excellent correlation of $r = 0.91$, $p < 0.001$ was established.

In summary, these results indicate that the NCCOM-3, rev. 6, estimate of cardiac output by thoracic electrical bioimpedance is similar to the use of thermodilution to assess cardiac output in most cases during the peripartum period in our study. Measurement of cardiac output by thoracic electrical bioimpedance is noninvasive, continuous, and requires no operator skill. Nevertheless, even if measurement of cardiac output by thoracic electrical bioimpedance is confirmed to be accurate in larger studies of pregnant patients, it must only be used as an adjunct to good clinical judgment.

In utero cocaine exposure: Observations of fetal behavioral state may predict neonatal outcome

Roderick F. Hume, Jr., MD, Maj, MC, USA,[a] Karen J. O'Donnell, PhD,[b,c] Cathi L. Stanger, RN,[a] Allen P. Killam, MD,[a] and Jeannine L. Gingras, MD[b]
Durham, North Carolina

Components of fetal behavioral state organization reflect the successful integration of the central nervous system, have a specific developmental timetable, and can be studied with fetal ultrasonographic techniques. To test the hypothesis that evaluation of state organization is a marker of abnormal central nervous system maturation and a predictor of risk, we studied 20 fetuses and newborns exposed to cocaine in utero. Fetal assessments were accomplished by serial ultrasonographic examination, videotaped, and scored by a scheme developed by the authors to assess organization and regulation of behavioral states. Newborn neurobehavioral assessments also emphasized organization and regulation of behavioral state. Abnormal or delayed state behavior was identified in 13 of 20 fetuses. State organization was evaluated as suspect or abnormal for 16 of the 20 exposed newborns. Disorganized behavioral state in the fetus successfully predicted abnormal newborn behavior. These findings support the concepts that cocaine exposure disrupts central nervous system development and that fetal assessment of state is predictive of neonatal outcome. (Am J Obstet Gynecol 1989;161:685-90.)

Key words: Cocaine, fetal behavioral state, state organization, neonatal state

Cocaine abuse is a major problem in our society. Its increasing use as the recreational drug of choice among the poor and the affluent has been responsible for an explosion of awareness of its potential for devastating addiction and medical catastrophe.[1] Cocaine use is also increasing among the reproductively active in our society. Cocaine use in pregnancy is associated with poor perinatal outcome: increased incidence of premature labor and delivery, intrauterine growth retardation, abruptioplacentae, stillbirth, maternal and neonatal intracranial hemorrhage, fetal distress, and altered neonatal behavior.[2-5] Also alarming is the possibility of an increased incidence of sudden unexplained infant death in the offspring of cocaine-abusing women.[2]

Neonates born to mothers who abuse cocaine during pregnancy have been shown to exhibit altered behavioral state organization in concert with poor perinatal outcome.[2,3,5] We have made the additional observation of a similar disorganization of fetal state-related behavior. State organization is seen as reflecting proper integration of the central nervous system, and we theorized that state organization or disorganization would be an early fetal marker of neurobehavioral risk. The present study investigated two hypotheses: (1) fetuses exposed to cocaine in utero would demonstrate altered behavioral state organization and (2) altered fetal behavioral state would be an early marker of the integrity of central nervous system maturation. This manuscript reports the observations on a cohort of perinates whose mothers abused cocaine during gestation and who were serially observed in utero with ultrasonography. The infants were examined in the neonatal period.

Material and methods

Duke University Medical Center provides the primary obstetric service for urban Durham and the surrounding rural counties. During the year of this study, there were 2245 deliveries at the medical center. Twenty women identified as cocaine users through clinic referral or self-referral volunteered and were enrolled in this institutionally approved study. The history of maternal substance abuse was obtained by the primary author (R. F. H.) serially and concurrently throughout prenatal care. The prospective, nonpunitive ascertainment of drug use allowed more information to be gathered relative to the timing and pattern of maternal substance abuse. The pattern of maternal substance abuse was obtained by interview and recorded for all of our subjects during their prenatal care and at delivery. Systematic drug screening was not an aspect of this study design. Serial ultrasonographic evaluations of fetal growth, well-being, and state-related behavior were recorded as a component of their

high-risk obstetric care. Subjects only identified at delivery as using cocaine were excluded from this report. This study reports on the observations of 20 fetuses serially evaluated in utero and followed through the neonatal period. No subjects were lost to follow-up. One infant delivered at term, who was examined in utero and after birth, died at home at age 21 days of *Klebsiella* sepsis.

Routine ultrasonographic evaluations included standard morphometric assessments of fetal weight, growth,[6] and well-being.[7] Our assessment of fetal behavioral state was adapted from techniques previously described by Nijhuis et al.[8] and Arduini et al.[9] Components of fetal behavior assessed included fetal heart rate variability, breathing motion, body tone and movements, and chin, mouth, and eye movements. Organization and regulation were defined as the coordination of related components of fetal behavior in a stable yet responsive state. Our modification, "Fetal Neurobehavioral Profile" (in preparation), emphasizes behavior state differentiation, organization, and regulation through systematic observations of unperturbed fetal behavior, effect of vibroacoustic perturbation, and the fetus' attempt at self-regulation after perturbation. The ultrasonographic technique requires an image of the fetal face, chin, and chest to allow coincidental evaluation of fetal eye, mouth, breathing, and heart motion. We used a GE RT 2600 device with 3.5 and 5 MHz linear array transducers to obtain a split-screen, real-time B-mode and M-mode image of fetal behavior, which was recorded on standard VHS format for later review. The stable association of rapid eye movements, chin motion, breathing, and reactive heart rate pattern is scored as active sleep. The stable association of no eye movements, chin motion, or breathing with a nonreactive heart rate pattern is scored as quiet sleep. After a 10- to 15-minute period of observation of unperturbed fetal behavior, vibroacoustic stimulation was applied in either of these stable behavioral states during direct ultrasonographic imaging with a brief (<1 second) stimulus from a Bell Laboratory artificial larynx. The fetal stimulus-response pattern was repeated to evaluate fetal habituation to sound perturbation. Fetal behavior was scored from video tape recorded ultrasonographic observations. Rating of fetal neurobehavioral profile was initially made at each ultrasonographic evaluation and recorded prospectively (R. F. H., C. L. S.). Prenatal data, including pattern of drug use, were recorded prospectively and stored in files coded to protect subject confidentiality.

Maternal and neonatal charts were reviewed to record obstetric and neonatal complications and outcome (C. L. S.). Gestational age and growth were evaluated to determine the appropriateness of growth for gestational age. Neonatal neurobehavioral assessment was accomplished between days 1 and 3 and before dis-

charge by an examiner (K. O. D., J. L. G.) who was blinded to pattern of maternal substance abuse, fetal behavioral profile results, intrapartum course, and drug screen results, if obtained. Because a history of cocaine exposure is an indication for referral for neonatal neurobehavioral testing, these examiners were not blinded to cocaine exposure. The neonates were assessed with methods described by others[10, 11] in the following areas: autonomic stability, motor status, reflex profile, state organization, and attention to auditory and visual stimuli. Overall neurobehavioral status was scored for these analyses as normal, suspect, or abnormal. Newborn state organization scores, classified as normal or abnormal for gestational age, were also analyzed. The reliability of fetal assessment to predict newborn assessment was accomplished by nonparametric means (χ^2). Other data are reported by frequency and proportion scores.

Results

Subjects. In our obstetric community 35 of 2245 deliveries (1.6%) were recorded as being complicated by maternal substance abuse. No systematic study for urine toxicology was done to obtain true prevalence during this period. Ten of these 35 (28%) received no prenatal care or received prenatal care outside of our clinic system. Additionally, five (18%) received prenatal care within our clinic system but were not able to be enrolled in our study because of logistic problems. Therefore 20 of the 35 women (54%) participated in this study. The timing of gestation at cocaine exposure, the use of other agents, and the mode of cocaine use are summarized in Table I. All subjects were exposed during the first trimester. Most attempted to discontinue their cocaine use on discovery of their pregnancy.

Table II lists the medical and obstetric complications experienced by our total cocaine-exposed cohort and compares them with the complications in a population of 2210 mothers not known to abuse cocaine who were delivered during the study period. Comparisons of these proportions indicated that significantly more women who abused cocaine had spontaneous premature rupture of the membranes ($p < 0.05$). The 20 infants evaluated in this study were born between 37 and 40 weeks of gestational age.

Fetal behavioral state organization. Abnormal fetal state-related behavior was identified in 13 of 20 neonates (65%) exposed to cocaine in utero who survived beyond midgestation. Our observations included both short-term (during maternal cocaine intoxication) and long-term (during maternal abstinence) effects on fetal behavior. This information is presented in Table III.

Manifestations of acute fetal intoxication were observed in three fetuses and included hyperflexion, irritability, prolonged periods of scanning eye movements during vigorous, almost continuous sucking, and excessive fetal motion, especially in response to stimulation. Fetal tachycardia and extreme baseline heart rate variability were most often evident on fetal heart rate testing. Of these three fetuses, two were also observed during acute maternal cocaine withdrawal. The fetal withdrawal effects were similar to the maternal symptoms of cocaine withdrawal with recurrent-repetitive yawning and problems of arousal most apparent. The fetus appears to experience concordant physiologic and behavioral effects along with its mother in response to cocaine.

Long-term or delayed effects of cocaine exposure were defined as delay or disruption of state organization, occurring in 13 of the 20 (65%), or as unusual fetal behavior, such as recurrent-repetitive yawning seen in three fetuses. A deep sustained, regular, hyperpneic (deep inspiratory cycle = expiratory cycle) fetal breathing pattern was seen in three fetuses. This latter pattern resembled the central neurogenic hyperventilation described in adults. Both the recurrent yawning and sustained hyperpneic breathing patterns persisted between behavioral states.

Six fetuses (30%) were assessed as growth-retarded on fetal ultrasonographic evaluation. Additionally, disorganization of fetal behavior appeared to be associated with the magnitude of maternal cocaine abuse (see Table III), although the relationships were not statistically significant.

Neonatal outcome. Newborn infants were assessed for overall neurobehavioral well-being in the areas of autonomic stability, motor and reflex status, state organization, and attentional capacities. The most frequent indicators of autonomic instability included excessive tremulousness in extremities, unexplained tachypnea, or both. Disrupted state organization was evidenced by hyperresponsiveness and by difficulty in

arousal. These infants often were seen as "all or nothing," that is, difficult to arouse, inconsolable when aroused, and having brief or no periods of quiet alertness. Deficits in attentional capacities (response to auditory and visual stimuli) usually were interpreted as being secondary to disrupted behavioral state regulation.

Overall neurobehavioral status was scored as normal, suspect, or abnormal (Table IV). Ten infants (50%) were neurobehaviorally abnormal, with nine scored as suspect and one scored as normal. It is important that fetal state organization successfully predicted overall newborn behavioral well-being ($\chi^2 = 6.2$; $p < 0.05$). For example, of the 13 fetuses seen as exhibiting abnormal state behavior, nine were abnormal and none were scored as normal newborns.

Newborn state organization, rated as organized (normal) or disorganized (abnormal), was abnormal in 16 of the 20 infants, again successfully predicted by the fetal state assessment ($\chi^2 = 9.2; p < 0.01$) (Table V). All 13 fetuses who had abnormal fetal state behavior were abnormal in state organization as newborns. Additionally, disorganization of neonatal behavior appeared to be associated with the magnitude of maternal cocaine abuse, although the relationships were not statistically significant. However, we did detect fetal and neonatal behavioral abnormalities even if exposure was limited to the first trimester.

Comment

These observations suggest that maternal cocaine usage results in both short-term (immediate) fetal and long-term postnatal effects. Short-term effects include manifestations of fetal intoxication (hyperflexion, irritability, excessive fetal movements, and sucking with fetal tachycardia and extreme baseline heart rate variability) and withdrawal (recurrent yawning and sustained hyperpnea). Long-term effects include intrauterine growth retardation and fetal neurodevelopmental delay or disruption as defined by altered fetal behavioral state organization and regulation. Since altered fetal behavioral state is associated with adverse perinatal outcome, our data strongly support a role for cocaine as a neurodevelopmental teratogen. The purpose of the current study was to test the hypothesis that altered fetal behavior could be detected ultrasonographically and that such abnormal fetal behavior would predict subsequent abnormal neonatal behavioral testing in a cohort of cocaine-exposed pregnancies. Prospective longitudinal study of these infants and matched controls is required to determine the significance of the delay or disruption of state organization identified with the fetal neurobehavioral profile.

Fetal behavioral states show a normal ontogeny with progressive coincidence of components of behavior becoming organized into clearly defined and stable patterns with maturity. This maturation has been described by Nijhuis et al.[8] and correlates with the behavioral states of the newborn. The progressive organizational, integrative, and interactive ability of the fetus with advancing gestational age serves as the foundation of newborn neurobehavioral examinations.[10, 11] Similarly, the correlation of fetal behavioral state with fetal biophysical parameters such as breathing, heart

rate variability patterns, Doppler flow in umbilical vessels, and echocardiographic measures of hemodynamics reveals a progressive integration of function of numerous organ systems. This concerted coordination of normal physiologic action is under the control or modulation of the central nervous system.[12] Thus the application of fetal behavioral state assessment may serve as a useful screening test for appropriate neurodevelopment. Indeed, altered fetal behavior has been described in animal models after exposure to narcotics and other agents.[13] Delayed development of the integration of fetal behavioral states has also been reported in human fetuses suffering intrauterine growth retardation.[14, 15]

Animal models of altered fetal environments that are associated with fetal growth retardation often include rather marked elevations of endogenous catecholamines, especially norepinephrine.[16] This biogenic amine has also been identified as responsible for the acceleration of pulmonary maturation. The peripheral nervous system and autonomic nervous system in these fetuses also exhibit advanced maturity when compared with normal fetuses. However, the development of the fetal central nervous system is disturbed and predominantly delayed in its ontogeny.[17] Cocaine may have similar effects on the developing fetus that are secondary to altered norepinephrine metabolism. This discordance of developmental achievement between the central nervous system–autonomic nervous system may be operative in the inappropriate response of these fetuses to environmental perturbation: fetal distress, stillbirth, neonatal transitional difficulties, and sudden unexplained infant death.

We have observed a similar disruption (disorganization) of fetal behavioral state organization and regulation associated with maternal cocaine use. Alterations in fetal behavior were manifested by dissociation or lack of coincidence of components of behavioral state, as well as an apparent delay in the onset of integration. Both short- and long-term neurodevelopmental effects of maternal cocaine abuse were observed. Immediate drug-induced responses included hyperrigidity in extreme flexion, hyperactivity with violent total body movements in response to stimulation, scanning eye movements to the exclusion of the normally predominant rapid eye motion, and marked alteration in fetal breathing patterns and fetal heart rate variability. Additionally, the short-term response appeared to correlate with the known kinetics of cocaine metabolism and degradation. We also noted a return to a more normal fetal biophysical profile and behavior the day or two after maternal cocaine ingestion. Although the most significantly impaired fetus was that of a chronic, multiple agent intravenous drug abuser who continued her daily use up to delivery, we discovered similar atypical behavior in the episodic user whose use was confined to the first trimester.

The explanation for persistent abnormalities in the episodic user may relate to the direct central nervous system–autonomic nervous system actions of cocaine, or a metabolite, on catecholamine uptake kinetics.[18] Such neurotransmitter effects could alter the ontogeny of neurotransmitter distribution or interfere with the normal development of the central nervous system. Alternatively, the hemodynamic effects of cocaine, mediated through norepinephrine, may be operative as a cause of growth retardation and delayed neurodevelopment.[19, 20] Further studies are necessary to evaluate these potential pathophysiologic mechanisms.

The dramatically increased incidence of cocaine-associated perinatal morbidity and mortality (impaired intrauterine growth, neonatal transitional dysfunction, and disorganization of behavioral states) reported in the literature is supported by our results. Additionally, we have observed altered behavior in those fetuses exposed to cocaine in utero. These data are in concert with the concept that cocaine alters central nervous system development. Fetal neurobehavioral assessment may serve as a useful screening test for intact neurodevelopment.

We thank Mrs. Mary Wade and Ms. Judi Goss for their assistance in the preparation of this manuscript.

In utero diagnosis of benign fetal macrocephaly

Robert DeRosa, MD,[a] Roger R. Lenke, MD,[a] Thaddeus W. Kurczynski, MD,[b] Wayne H. Persutte, BS, RDMS,[a] and Joanne M. Nemes, RNC, BSN[a]

Toledo, Ohio

Benign familial macrocephaly is an autosomal dominant disorder associated with a large absolute circumference of the head. In this disorder serial growth demonstrates a proportional rather than an excessive rate of growth. To date, we are not aware of any published case reports that confirm the diagnosis prenatally. We report a case of benign familial macrocephaly diagnosed in utero by ultrasonographic evaluation. This case report points out the necessity of combining appropriate family history and physical examination in cases of prenatally detected anomalies. (AM J OBSTET GYNECOL 1989;161:690-2.)

Key words: Prenatal diagnosis, benign familial macrocephaly

Macrocephaly is defined as an occipitofrontal head circumference >2 SDs above the mean or above the 98th percentile for chronologic age.[1, 2] Macrocephaly may be associated with hydrocephalus; neurocutaneous syndromes such as neurofibromatosis, multiple lipomas, and hemangiomas (Bannayan-Zonana syndrome), multiple hemangiomas (Riley-Smith syndrome); or benign familial macrocephaly. Benign familial macrocephaly is a common autosomal dominant trait in which the absolute circumference of the head is large, but serial measurements show a proportional rather than an excessive rate of growth.[3] It often occurs in normal individuals without demonstrable neurologic abnormalities.[1] We report a case of benign familial macrocephaly diagnosed in utero by a combination of prenatal ultrasonographic evaluations and family history.

Case report

The patient was a 21-year-old white woman, gravida 2, para 0, living children 0. Her previous laboratory evaluations included a blood type of AB, rhesus negative, a normal maternal serum α-fetoprotein level at 16 weeks' gestation (0.94 multiples of the median) and normal glucose tolerance test results at 30 weeks' gestation. Pregnancy dating was confirmed by an accurate last menstrual period and early pelvic examination at 12 weeks' gestation. Correct gestational age was also confirmed by an ultrasonographic evaluation at 21 weeks' gestation. This initial examination showed no discrepancy between head circumference (190 mm for 21.3 weeks' gestation), biparietal diameter (52 mm for 21.8 weeks' gestation), abdominal circumference (166 mm for 21.6 weeks' gestation), femur length (34 mm for 20.7 weeks' gestation), and humeral length (33 mm for 21.3 weeks' gestation). An ultrasonographic evaluation at 32 weeks' gestation was obtained because of a history of vaginal bleeding. Fetal measurements were as follows: biparietal diameter 96 mm (39 weeks' gestation); abdominal circumference 341 mm (38 weeks' gestation); femur length 64 mm (33 weeks' gestation); tibial length 58 mm (34 weeks' gestation). There was no evidence of fetal ascites or skin edema. The fetal lateral ventricle/hemispheric ratio was nor-

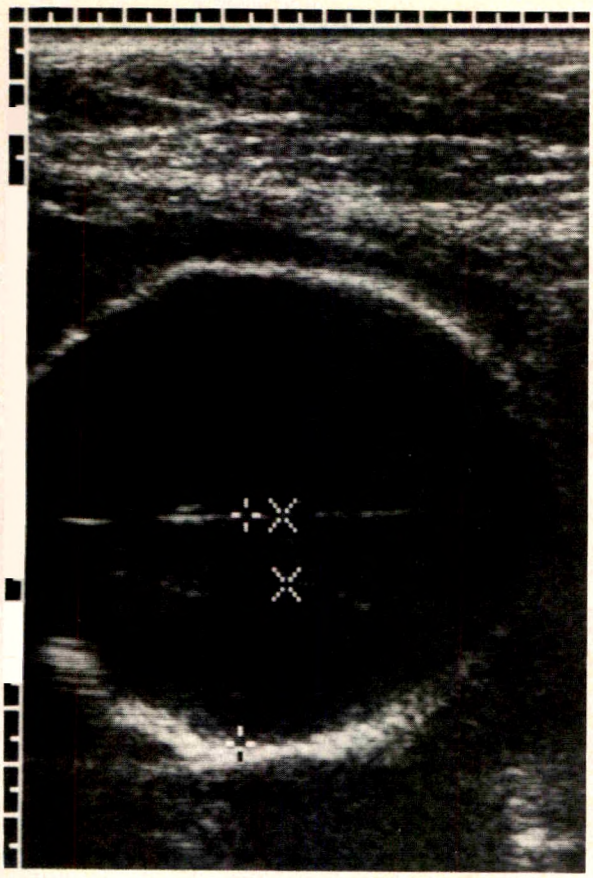

Fig. 1. Transverse view of fetal head at 33 weeks' gestation. No visible structural anomaly. (Lateral ventricle/hemispheric ratio is 31%.)

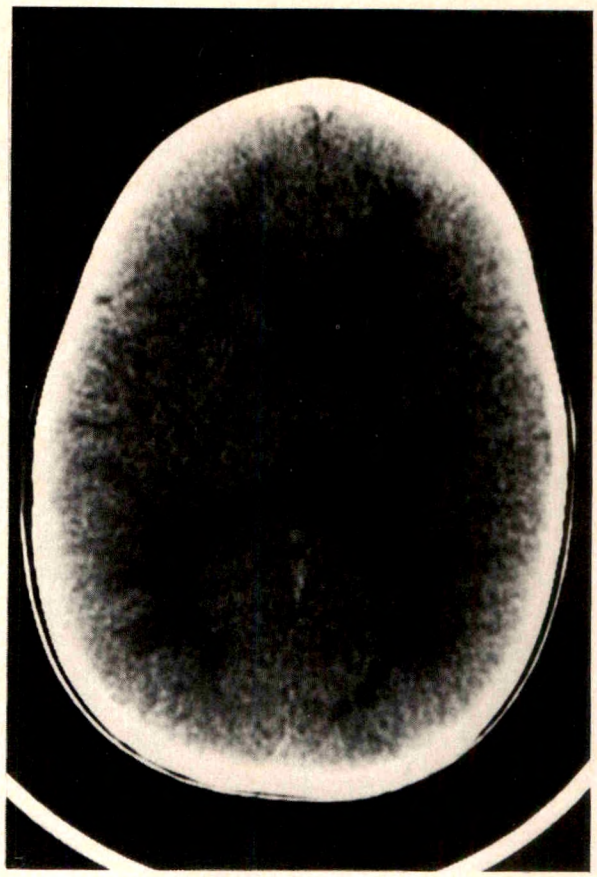

Fig. 2. Computerized axial tomography scan of infant's head at 8 months of age. No visible intracranial anomaly.

mal (31%) (Fig. 1). No other fetal abnormalities were identified. There was no evidence of placenta previa or abruptio placentae.

Physical examination of the patient showed a maternal height of 4 feet 11 inches and weight of 211 pounds. Maternal head circumference was 61 cm (>98th percentile). No other abnormalities were noted on physical examination. Review of the patient's family history revealed several maternal half-sisters of approximately the same height who were also reported to have "large heads." Physical examination of the patient's mother also revealed a head circumference of 61.2 cm (>98th percentile). Unfortunately, no other relatives were available for physical examination.

On the basis of this information, a diagnosis of benign familial macrocephaly was made. A follow-up ultrasonographic evaluation at 36 weeks' gestation showed a biparietal diameter of 102 mm (>40 weeks' gestation); head circumference of 369 mm (>40 weeks' gestation); abdominal circumference of 368 mm (>40 weeks' gestation); femur length of 72 mm (37 weeks' gestation); and fetal intracranial anatomy was normal with a lateral ventricle/hemispheric ratio of 29%.

The patient had suspicious antepartum test results at 39 weeks' gestation and an oxytocin induction was performed. The patient had a normal spontaneous vaginal delivery of a 4190 gm male infant with Apgar scores of 9 at both 1 and 5 minutes.

Evaluation of the infant at birth showed a head circumference of 37.5 cm (98th percentile) and a body length of 53 cm (90th percentile). No other physical abnormalities were detected. Follow-up evaluation of the infant at 6 months of age showed a normal neurologic evaluation but persistent macrocephaly. The head circumference was at the 98th percentile, and body length was at the 75th percentile with weight at the 90th percentile. A computerized axial tomography scan performed at 8 months of age did not show abnormalities (Fig. 2).

Comment

Our patient was initially referred to our facility with a diagnosis of possible fetal hydrocephaly. Our ultrasound evaluation confirmed an enlarged fetal head but found a normal relationship between the fetal ventricles and head size. The enlarged fetal head raised the possibilities of fetal macrocephaly versus fetal macrosomia, or possibly a combination of both.

In the obstetric literature, macrosomia is often de-

fined as a birth weight >4000 gm.[5] The in utero diaganosis is often made on the basis of a disproportionately large fetal abdominal circumference. In the present case, the infant had an abdominal circumference that was consistently large for dates. The birth weight was also >4000 gm. Thus, by definition, the infant was macrosomic. Previous publications, though, have not shown macrosomia to be associated with macrocephaly.[6] There was also a discrepancy between the fetal head size and long-bone measurements. Because this is the first reported case of prenatally diagnosed benign familial macrocephaly, one cannot say that infants with this condition will or will not be macrosomic.

There have been several case reports of benign familial macrocephaly published, but in all these previous cases the diagnosis was made after delivery.[1, 2, 4] To our knowledge, this is the first reported case of prenatally diagnosed benign familial macrocephaly. The benign nature of this diagnosis points out the necessity of obtaining an appropriate family history when ultrasonographic evaluation shows possible fetal abnormalities. The presence of known benign familial macrocephaly in either parent should alert the obstetrician and the ultrasonographer to look for this finding in the fetus. Only careful follow-up examinations will serve to distinguish this condition from other more serious disorders. If one does not include this benign condition in the initial differential diagnosis of an enlarged head, then one may cause undue anxiety for the patient.

Rapid determination of fetal sex by deoxyribonucleic acid amplification of Y chromosome–specific sequences

Thomas L. Pinckert, MD, Roger V. Lebo, PhD, and Mitchell S. Golbus, MD
San Francisco, California

Rapid fetal sex tests use either dot blot hybridization to Y chromosome–specific (male) repeat sequences or polymerase chain reaction deoxyribonucleic acid amplification of these Y-specific sequences. We have performed 35 fetal sex determinations, 16 by dot blot alone, 13 by polymerase chain reaction alone, and 6 by dot blot and polymerase chain reaction on samples of fetal blood, amniotic fluid, and chorionic villi. All results have been confirmed by karyotyping. Dot blots have given false-positive "male" results three times. In contrast, the polymerase chain reaction has correctly determined fetal sex in every case, even when the dot blot was in error. The Y-specific polymerase chain reaction has been applied to fetal deoxyribonucleic DNA with a chromosome 15; Y translocation to identify the origin of the translocated material. Thus the polymerase chain reaction appears to be a reliable method to rapidly determine fetal sex that also can be used diagnostically to identify translocated Y-chromosomal material. (Am J Obstet Gynecol 1989; 161:693-8.)

Key words: Y chromosome, DNA amplification, polymerase chain reaction

Prenatal determination of fetal sex is extremely important in the management of X-linked disorders.[1] Duchenne and Becker muscular dystrophy, hemophilia A and B, and the Lesch-Nyhan syndrome are among the 139 X-linked phenotypes in which fetal sex is an important factor in counseling. Previously, fetal sex determination relied on karyotyping amniocytes or chorionic villus cells. Standard karyotyping depends on obtaining multiple high-quality metaphases from cells cultured for days to weeks before analysis. Because karyotyping without tissue culture is not always definitive, efforts have been made to develop a prenatal sex test that is rapid, specific, and can be performed early in gestation.

The dot blot test developed by Lau[2] was used by our laboratory as an adjunct to karyotyping as part of our protocol to prenatally diagnose fetuses at risk for X-linked diseases. We used the dot blot protocol to test for repetitive sequences on the terminal portion of the long arm of chromosome Y. Repeated sequences are very useful to test small quantities of deoxyribonucleic acid (DNA) because the signal is amplified the number of times the sequence is repeated. Because the cloned 3.4 kb *Hae* III sequence hybridizes to approximately 2000 homologous sequences on the Y chromosome, small quantities of DNA can be tested without purification. A cloned *Alu* sequence hybridizes to approximately 300,000 homologous *Alu* sequences located ubiquitously throughout the genome. *Alu* is used as a control to establish that DNA has been recovered and applied to each dot (Fig. 1).

Subsequently DNA amplification of Y-chromosome–specific sequences was developed by Kogan et al.[3] The polymerase chain reaction protocol repeats a series of DNA denaturing, annealing, and elongation cycles 35 times (Fig. 2). This amplification synthesizes thousands of unique length copies of each original strand. This procedure has been used to diagnose sickle cell anemia[4] and β-thalassemia[5] with the use of primers that recognize and amplify unique gene sequences. The protocol has also been used to detect human immunodeficiency virus in peripheral blood lymphocytes[6] and is being applied to the detection of other viruses. We tested both the dot blot and polymerase chain reaction protocols on a series of pregnancies at risk for a fetus with an X-linked disease.

Chromosomal translocations in fetal cells have different implications depending on which translocated chromosomal regions remain and where the breakpoints occur. If extra chromosomal material results from a translocation, these regions generally carry active genes that make the cell aneuploid for those genes. Reciprocal translocations themselves carry a low but real risk because the correct number of genes is maintained and breaking and rejoining usually occur between active gene regions but may occur within genes

The *dot* in the lower left was used to orient the autoradiograph.

and alter gene function. Ideally, the precise rearrangement is identified by chromosome banding or by gene mapping to determine as accurately as possible the risk to the fetus. Herein we describe testing fetal DNA from an ambiguous karyotype for the presence of Y-repetitive chromosomal material to clarify the risk to the fetus.

Material and methods

Dot blot analysis. Cells from 1.0 ml of amniotic fluid or two chorionic villi are centrifuged and resuspended in 20 μl 0.1N sodium hydroxide–2 mol/L sodium chloride and 0.5% sodium dodecyl sulfate to disrupt the cells. After vortex mixing, the pellet is boiled 2 minutes at 100° C to complete DNA denaturation. Cellular debris is separated by Eppendorf centrifugation for 2 minutes. The supernatant is dotted onto nitrocellulose filter paper, dried, baked, prehybridized, and then hybridized to cloned Y-specific 3.4 kb *Hae* III fragments or ubiquitous repetitive *Alu* DNA probe overnight at 41° C in 50% formamide. The next morning the filters were washed and autoradiographed for 2 hours according to Lau[2] (see Fig. 1 for results).

Polymerase chain reaction amplification. DNA is prepared and denatured from amniocytes or chorionic villi as above. Samples of approximately 0.5 μg male and female DNA are included as controls. The reaction mix consists of denatured DNA, 25 pmol each of two Y-specific oligonucleotide primers,[2] 1.5 mmol/L of each deoxynucleotide triphosphate, 5 U *Taq* polymerase, 67 mmol/L Tris hydrochloride (pH 8.8), 16.6 mmol/L ammonium sulfate, 6.7 mmol/L magnesium chloride, 6.7 mmol/L ethylenediaminetetraacetic acid, and 170 μg/ml bovine serum albumin.[3] A control reaction mix is included in which 25 pmol each of both *Alu* oligonucleotide primers has been substituted for the Y-specific primers. Samples are amplified for 35 cycles on a Perkin-Elmer/Cetus instrument. Samples are denatured initially for 2 minutes at 94° C. The 35 cycles each include a 30-second denaturation step at 92° C, a 25-second annealing step at 40° C, and a 25-second elongation step at 65° C. The amplified reaction mix is loaded on 12% polyacrylamide gel and electrophoresed for approximately 2 hours at 100 V. The separated DNA fragments are visualized by staining with ethidium bromide and destaining before photography (see Fig. 2).

Biquinacrine staining. Mounted G-banded chromosome slides were recovered by dissolving the mounting medium in xylene. Slides were then stained in 0.002% biquinacrine hydrochloride for 3 minutes and destained in running distilled water 4 minutes.

Results

The dot blot protocol was applied to 22 samples. Usually male DNA hybridizes more intensely to the 3.4 kb Y probe than control female DNA to unambiguously establish the sex of the DNA tested. However, in 3 of 22 cases the homologous repetitive sequences on the autosomes hybridized sufficiently to the repetitive Y-chromosomal DNA probe to give a "false-positive" or apparent male signal in fetal female DNA.

In the polymerase chain reaction test DNA is amplified with primers that synthesize male-specific 150 bp

fragments, different length autosomal fragments (Fig. 3, left), and repeated multiple length *Alu* repetitive sequences in the control reaction (Fig. 3, right).[3] We have used this protocol to analyze six samples tested by dot blot including the three that gave false-positive results, as well as 13 additional samples tested by the polymerase chain reaction alone. In each case the polymerase chain reaction gave the correct result. All results were verified by karyotyping. The polymerase chain reaction method routinely gave results in 1 or 2 working days and required less effort than the dot-blot method.

We have also applied this technique to identify the chromosomal origin of an extra chromosome fragment translocated to the short arm of chromosome 15 in an XX fetus (Fig. 4). Giemsa banding showed that this chromosome segment was heterochromatic and probably derived from chromosome 1, 9, 16, or Y. The portion of chromosome 15 deleted by the translocation carries ribosomal genes that are duplicated in the other nine acrocentric chromosomes so that this deletion would not be detrimental. DNA from the cultured cells was extracted and tested by the polymerase chain reaction. An amplified 150 bp Y-specific DNA fragment was identified in the fetal DNA (data not shown). Dot blot analysis was consistent with this finding. This result established that the extra chromosomal fragment was from the Y-chromosome heterochromatin, a reassuring finding. To further confirm this result, we used biquinacrine stain to restain chromosomes that had been banded with Giemsa. Enhancement of the repetitive Y-chromosome region fluorescence is several

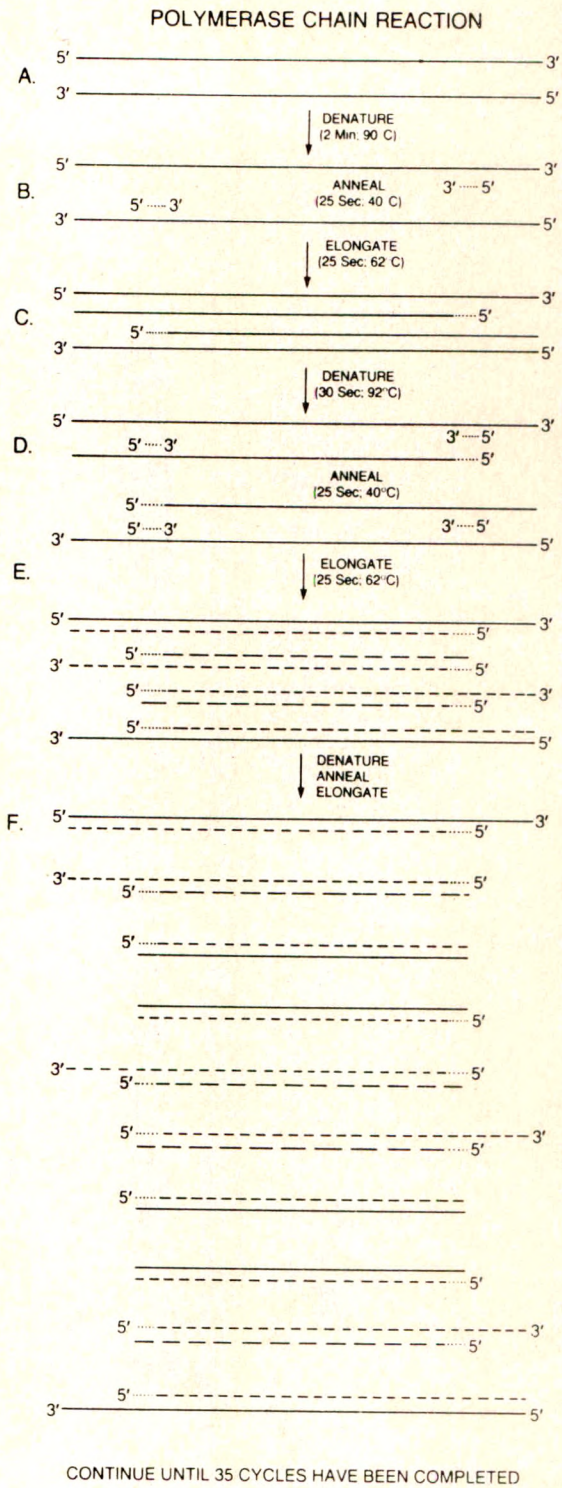

Fig. 2. For legend see left-hand column.

Fig. 2. Polymerase chain reaction scheme. $A \rightarrow B$, Double-stranded DNA is denatured by high temperature (90° C for 2 minutes) into two single strands. *B*, The temperature is lowered to allow sequence-specific primers to stick (anneal) to highly homologous DNA segments. *C*, The original denatured DNA strands act as the elongation templates to extend the primers. Nucleotides and DNA polymerase are added to the primers to synthesize complementary DNA strands. Two primers are required to direct DNA synthesis because the DNA polymerase moves only in a $5' \rightarrow 3'$ direction and both strands must be primed. This step synthesizes two copies of the chromosomal region of interest. The duration of elongation determines the length of the synthesized fragments. $D \rightarrow E$, In turn, these two double-stranded daughter copies are denatured, reannealed, and elongated to form four new copies of double-stranded DNA (again only in the chromosomal region of interest). Note that these include the two original gene strands, four longer amplified copies that extend beyond the reverse primer recognition site, and two unique length amplified copies. $E \rightarrow F$, By repeating this process the next cycle yields the two original gene strands, six longer amplified copies, and eight unique length amplified copies. This process is repeated multiple times to logarithmically increase the number of unique length sequences.

times greater with biquinicrine than with quinacrine. As expected, the Y-chromosome–specific region translocated to the short arm of 15 stained very brightly (Fig. 5). This result further confirmed the polymerase chain reaction result that repetitive Y-chromosome sequences were carried by this patient. The gene for the

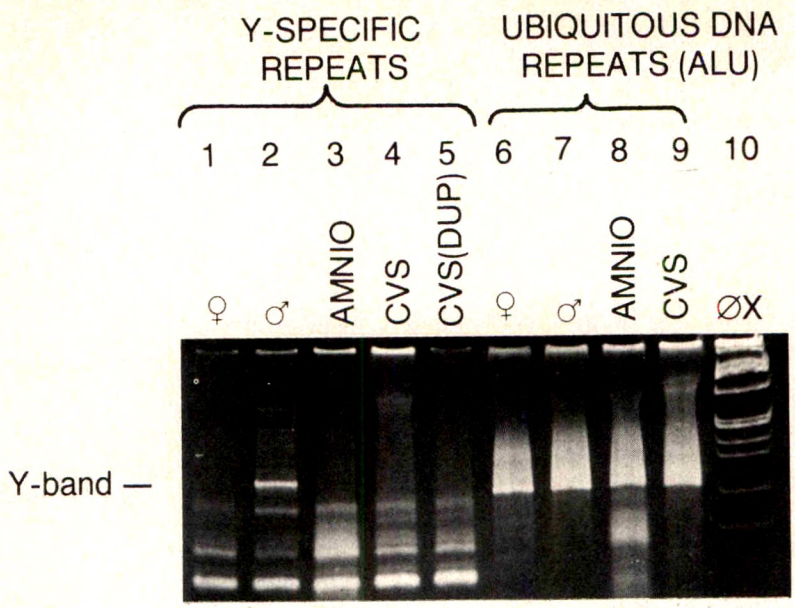

Fig. 3. Photograph of polyacrylamide gel electrophoresis illustrating the polymerase chain reaction protocol. Lanes *1* to *5* were amplified with Y-chromosome repeat primer and lanes *6* to *10* with ubiquitous repetitive *Alu* primer to verify DNA amplification in each sample. Lane *1* is control female DNA from lymphocytes, lane *2* is control male DNA from lymphocytes, lane *3* is unknown amniocyte DNA (female), and lanes *4* and *5* were a chorionic villus DNA sample (female) tested in duplicate. Note the bright Y-specific band identified in lane *2*.

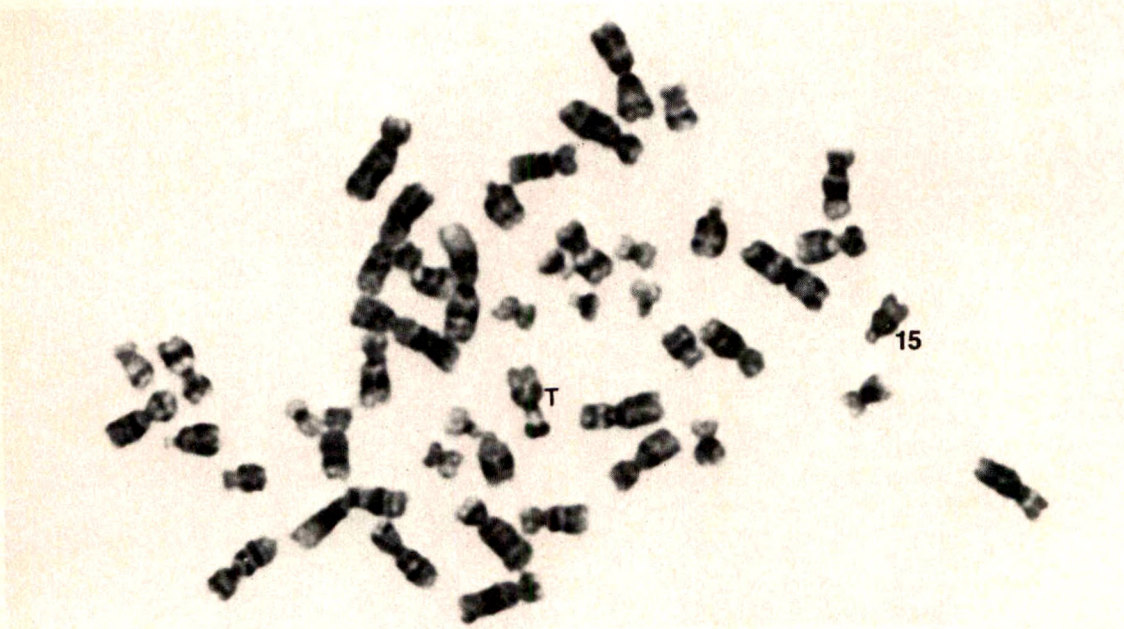

Fig. 4. Giemsa-banded chromosome analysis. One translocated chromosome 15 *(T)* has a G-positive segment translocated to the short arm while the other chromosome 15 *(15)* is normal. Since Giemsa banding does not distinguish the origin of this extra chromosomal material, this karyotype designation is 46,XX, − 15, + t(15;?)(p13;?).

testis-determining factor has been reported to be on the short arm of the Y chromosome. A sonogram of the fetus was consistent with female genitalia. We interpret these data to indicate that the extra Y-chromosome material in this female fetus represents a minimal phenotypic risk.

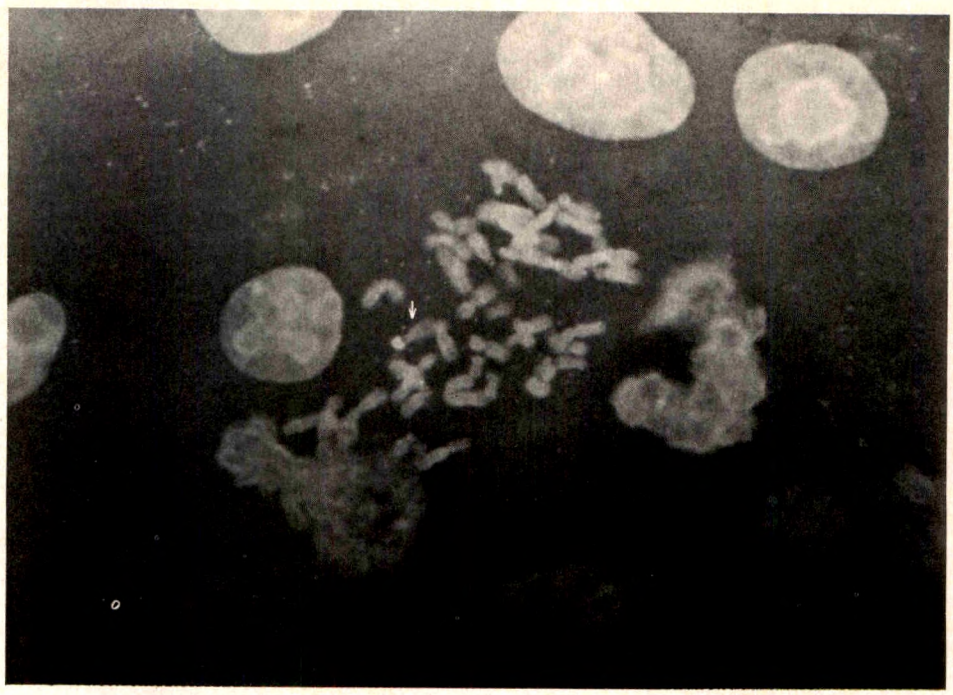

Fig. 5. Biquinacrine-banded chromosome analysis. The translocated chromosome 15 indicated by the *arrow* carries a brightly staining chromosome region typical of the inactive repetitive region of the Y chromosome. This result confirms that the karyotype is 46,XX,−15,+t(15;Y)(p13;q12).

Comment

Polymerase chain reaction is a rapid and sensitive method to analyze a specific DNA sequence. Sequence-specific oligonucleotide primers are extended by *Taq* polymerase isolated from *Thermus aquaticus*. Because this bacterium grows well in hot springs, all of its enzymes have adapted to become heat resistant. Thus DNA can be denatured repeatedly at high temperature in the presence of *Taq* polymerase without destroying polymerase activity. In addition, improved fidelity is maintained during elongation at higher temperatures. (See Fig. 2 for further details.) Polymerase chain reaction has been applied to analyze the DNA contained in as little as 10 μl of amniotic fluid,[2] a single chorionic villus (our laboratory), or a single cell equivalent[7] (our laboratory). The amount of DNA needed for polymerase chain reaction is small enough that an amniocentesis sample or chorionic villus sample is sufficient for both polymerase chain reaction and any other cytogenetic or biochemical test required. The test is rapid because the DNA polymerase generates thousands of duplicate fragments in hours. The amplification is not only quite efficient (50% to 90% duplication per cycle) but highly specific as it amplifies the sequences representing only 0.04% of the total DNA added to the reaction mix.

In contrast to the specificity of polymerase chain reaction, the dot blot test originally used for fetal sex determination gave false-positive results on three occasions. The dot blot assay depends on the quantitative hybridization of the Y-repetitive probe to Y-specific sequences. However, cross hybridization to autosomal sequences in female DNA decreases the ability to differentiate a male-specific signal. Repeat sequences located immediately beneath the centromere on chromosome 15 have been found to hybridize to the Y-repetitive probe at the assay conditions used. The size of this chromosome 15 region has been demonstrated to be normally variable by DIPI [4′,6-*bis*(2′-imidazolinyl-4′-5′H)-2-phenylindole] staining of distamycin A–stained chromosomes[8] and confirmed by flow analysis of chromosomes.[9] The heterochromatic region of chromosome Y is also known to vary substantially in size in normal men. Differentiating two large chromosome 15 repeat sequence regions in a female from a small heterochromatic Y-chromosome region can be difficult. These normal variations in size probably account for the false-positive results.

The application of polymerase chain reaction is uncomplicated and in most cases generates a result in 4 to 6 hours. The utilization of heat-stable *Taq* polymerase and a programmable polymerase chain reaction machine minimizes laboratory effort and makes this assay routine. The ability to obtain a rapid, accurate sex determination allows families at risk for an X-linked disease more time to make decisions regarding the fetus. It also reduces pressure on laboratory personnel with a heavy workload who need to prioritize diagnostic

tests. These characteristics make polymerase chain reaction sex testing an ideal tool for prenatal studies. Future applications of this technique will be limited only by the number of genes cloned and sequenced and by the imagination of the investigators studying them.

We thank Robert Flandermeyer for biquinacrine staining, Dr. Steven Schonberg for Giemsa-banded karyotypes, and Drs. James Goldberg and Robert Anderson for patient's samples. We thank C. C. Lin for his generous gift of biquinacrine hydrochloride.

"Possibly" de novo translocations: Prenatal risk counseling

E. Robert Wassman, MD, Debra L. Cheyovich, DrPH, and Yasunori Nakahara, MD

Pasadena, California

De novo rearrangements incidentally found at prenatal diagnosis may carry an increased risk of abnormal outcome. Situations in which the paternal chromosomes cannot be analyzed (e.g., artificial insemination, nonpaternity, deceased or otherwise unavailable father) are only "possibly" de novo. In our series of 23,495 prenatal diagnoses we unexpectedly found 67 balanced translocations. Of these, 26 were Robertsonian and 41 were reciprocal. A total of 45 (67%) of these translocations were inherited, and 19 (28%) were apparently de novo. Inherited translocations were maternal in 25 cases (55%) and paternal in 20 cases (45%). Follow-up was available in 87% overall, and revealed abnormal outcomes in 2/15 de novo cases, and 2/38 inherited cases. We suggest that 10% may be a reasonable estimate of risk for de novo translocations found at prenatal diagnosis. Given the observed distributions of inherited cases, a lower risk of abnormal outcome should be counseled in "possibly" de novo cases. (Am J Obstet Gynecol 1989;161:698-702.)

Key words: De novo translocations, prenatal diagnosis, paternity

The occurrence of mental retardation or malformations in persons with apparently balanced translocations has been well documented.[1,2] The excess of such translocations that are de novo in populations of the mentally retarded,[3,4,5] as compared with general newborn surveys[6,7] has suggested that such noninherited rearrangements are the cause of the impairment in those individuals. Submicroscopic chromosome loss, position effect, and breakpoint site mutations have been suggested as plausible hypotheses to explain this observation.[1]

The widespread use of prenatal cytogenetic diagnosis for advanced maternal age and other indications[8,9] has predictably lead to numerous cases of incidental detection of apparently balanced translocations in the fetus. This finding requires parental chromosome analysis and accurate genetic counseling. Generally, translocations inherited from a normal parent have been considered to carry little or no inherent risk of abnormal outcome. However, on the basis of the surveys

cited previously, de novo rearrangements have been considered to carry an increased risk that remains poorly defined despite Warburton's (1984)[10] collaborative study of such cases.

Situations in which the paternal chromosomes cannot be analyzed can further confound the genetic counseling. Artificial insemination, nonpaternity, death of the father, parental separation, non-pair-bonded coupling, and extended travel may all be potential causes for the problem of the "possibly" de novo translocation. Experience with several such cases and the belief that they should be counseled at a lower risk than that for established de novo cases prompted us to review our experience in a private prenatal diagnostic center.

We have used detailed information on the 67 apparently balanced translocations found incidentally among 23,495 consecutive prenatal cytogenetic studies at The Genetics Institute between 1981 and 1987, and conducted follow-up surveys on those cases. These data are compiled with other similar series to attempt to obtain a reasonable calculation of the risk of abnormal outcome.

Material and methods

The Genetics Institute is a private practice of medical genetics including prenatal diagnosis and other clinical and laboratory services. All records of The Institute's cytogenetic laboratory in Pasadena, California, were systematically reviewed and compiled from its founding in 1981 through the end of 1987.

Approximately 25% of referrals use the Institute as a reference laboratory, whereas the remainder represent cases from our clinics. Cases are routinely analyzed with quinacrine dihydrochloride fluorescence banding by established methods.[11] A maternal blood sample is cultured along with each case and analyzed when needed.[12] For this study, all cases in which a nonmosaic apparently balanced translocation was found were reviewed in detail. Cases in which an unbalanced rearrangement was found were not considered, nor were cases in which the indication for amniocentesis was for a known familial translocation. A total of 67 cases of such incidentally found balanced translocations were encountered among the 23,495 prenatal diagnoses reviewed. The parental chromosome analyses were similarly reviewed and the cases were divided into three categories—inherited, de novo, and unknown.

No infants or abortuses were examined by the authors in this process. Systematic telephone follow-up with regard to malformations and developmental milestones with either the delivering obstetrician, subsequent pediatrician, or patient was attempted in all cases in addition to our routine postnatal follow-up form requested from referring physicians. Cases were considered for outcome classification based on the status at the point of longest follow-up. Therefore in a case in which difficulties were encountered at term but the infant subsequently demonstrated normal growth and development and was without malformations noted, the outcome was considered normal.

Table I. Distribution of balanced translocations incidentally found at amniocenteses

	Maternal	*Paternal*	*De novo*	*Unknown*	*Total*
Reciprocal	15	11	13	2	41
Robertsonian	10	9	6	1	26
TOTAL	25	20	19	3	67

Results

In our series of 23,495 prenatal diagnoses (mean age = 36.6 years), 67 balanced nonmosaic translocations were incidentally found. Only 12 additional instances of balanced translocations were found in patients referred because of a known familial balanced translocation, and these were excluded from the present study. The primary indication for amniocentesis (47/67) was advanced maternal age. The mean maternal age for inherited and de novo cases were 34.7 years old and 35.5 years old, respectively. Five patients were referred because of abnormal maternal serum α-fetoprotein results—four high and one low. Three cases were from twin gestations; one of which was dizygotic based on discordance of the translocation finding.

Of the 67 translocations studied, 26 were Robertsonian and 41 were reciprocal. A total of 45 (67%) of the translocations were inherited from a parent and 19 (20%) were presumed to be de novo on the basis of parental chromosome studies (Table I). Inherited translocations were from the mother in 25 instances (55%) and from the father in 20 instances (45%).

The Robertsonian translocations were predominantly (73%) 13q14q, of which 26% were de novo. The next most frequent Robertsonian translocations were 14q21q (three cases) and 14q15q (two cases). Only the 13q22q and 15q21q possible Robertsonian combinations were not observed. No X-autosome translocations were observed in this series. Other cytogenetic abnormalities were seen in five cases: two cases of pericentric inversion of chromosome 9; two of trisomy 21; and one of trisomy 18.

Follow-up information was available in 87% of all cases (58/67), and 95% of de novo cases (18/19). In the inherited group, aside from two cases terminated because of a concomitant trisomy found, no elective terminations of pregnancy occurred. Of the remainder of the familial cases, one infant who was apparently

Table II. Follow-up: De novo and unknown cases

De novo	*Outcome*	*Unknown*	*Outcome*
t(10;18)	Normal 3 yr female	t(14q15q)	Normal newborn 6 lb 15 oz male
t(8;15)	Normal 3 yr female	t(13;14)	No data

t(15;17)	Elective abortion because of trisomy 21		
t(2;14)	Normal 7 mo male; placental defect, abruptio placentae, disseminated intravascular coagulation at birth		
t(3;20)	Normal 6 mo male; mild micrognathia at birth		
t(6;22)	Normal newborn male		
t(15;19)	Normal newborn 6 lb 13 oz male		
t(4;8)	Elective abortion		
t(4;16)	Normal 3 yr female		
t(1;11)	Normal newborn male		
t(1;13)	Normal newborn 8 lb female		
t(6;8)	No data		
t(13q14q)	Normal 3 ½ yr male		
t(13q14q)	Elective abortion because of neural tube defect		
t(13q14q)	Elective abortion		
t(14q21q)	Normal newborn 8 lb 6 oz male		
t(13q14q)	Normal 7 mo male		
t(13q14q)	Fetal death; Rh factor sensitization(?)		

normal at birth subsequently had developmental delay, and another had ascites detected prenatally and was born prematurely with intrauterine growth retardation, hepatosplenomegaly, and ascites, presumably all of viral etiology.

In the de novo group (Table II), two patients elected to terminate their pregnancies without abnormalities noted by ultrasonography. Fetal examinations were not possible in these patients. One patient terminated the pregnancy because of a concomitant finding of trisomy 21. Another patient underwent an elective abortion because of a neural tube defect detected by ultrasonography and α-fetoprotein analysis. A single fetal death occurred that reportedly was a result of rhesus factor sensitization. Of infants carried to term, we have specific follow-up data for ≥3 years in four cases and 6 months to 1 year in four more cases, without any abnormal outcomes noted. One case with a placental defect detected by ultrasonography and abruptio placentae disseminated intravascular coagulation at term, has subsequently done well, and another with mild micrognathia at birth has similarly developed normally.

Normal follow-up results were available on two thirds of the "possibly" de novo cases.

Comment

The incidental detection of an apparently balanced chromosomal rearrangement at prenatal diagnosis can be extremely discomforting to a patient who expects "clear cut" normal results versus abnormal results. The reassuring value of finding the same structural aberration in a parent is immeasurable. Uncertainty clearly remains in cases of de novo rearrangements and in situations in which the father or rarely both parents cannot be studied. Unavoidable circumstances, social situations in present-day society, and increased use of artificial insemination donors may be expected to increase the number of such "possibly" de novo cases, and it is necessary to provide a reasonable approach to counseling in these situations. We therefore conducted this follow-up survey from a single very large center and compiled it with comparable data from the literature to attempt to provide such information. We focused solely on translocations; however, similar problems arise with other types of chromosomal rearrangements and rare variants.

In our prenatal diagnosis population we found a rate of presumed de novo translocations of 0.8:1000. This is slightly higher than the previously reported rates from amniocenteses.[13-15] This may reflect the more complete ascertainment of parental carriers than is possible in collaborative studies,[14, 15] and the larger numbers in our series than in previous single center studies.[13] This rate is twofold to threefold higher than that observed in newborn surveys.[6, 7] Inasmuch as the mean age of our de novo group (35.5 years) is advanced and comparable to our prenatal diagnosis population (36.6 years), this may support a previous suggestion that the rate of de novo translocations is maternal age–dependent.[14]

It is of interest that none of our patients was referred because of a primary indication of exposure to potential teratogens or mutagens. This category was represented in excess in the series reviewed by Hook et al.[14] However, four cases of our 67 patients were referred because of elevated maternal serum α-fetoprotein values.

Table III. Clinical outcomes of incidentally discovered balanced translocations

Reference	Total cases	*Inherited*		*De novo*	
		Normal	*Abnormal*	*Normal*	*Abnormal*
Present study	23,495	37	2	13	2
Vejerslev and Friedrich[15] (1984)	5,547	14	0	2	1
Nielsen and Krag-Olsen[7] (1931)	11,148	24	3	5	0
Warburton[10] (1984)	76,952	—	—	53	4
TOTAL	117,142	75	5	73	7

Overall, the number of referrals because of abnormal maternal serum α-fetoprotein values are increasing as this test and ultrasonography are used as noninvasive indices of fetal abnormality and replace some of the older indications as the primary reason for referral.[16] In 1987, 14% (3/22) of our incidental balanced translocations were referred because of high maternal serum α-fetoprotein values, whereas only 3.9% of the total referrals in that year were because of this reason. Only one of our four cases was a de novo translocation, which corresponds with the percentage of de novo cases in our total population (28%).

Although the numbers are too small for meaningful statistical analysis, we observed a possible excess of balanced translocations in trisomic fetuses. Two cases of trisomy 21 were observed and one case of trisomy 18. One of the cases was concomitant with a de novo reciprocal translocation, whereas the other two cases were with a maternally derived reciprocal translocation and a paternally derived Robertsonian translocation, respectively. Two cases were also seen in which a pericentric inversion of chromosome 9 was found; however, in neither case was this variant inherited from the same parent as the translocation.

Our distribution of translocation types (Robertsonian/reciprocal = 0.63) is intermediate between previous amniocentesis series (Robertsonian/reciprocal = 0.25)[13-15] and newborn surveys (Robertsonian/reciprocal = 1.03).[6,7] Reasons for the differences are unclear.

Our series reflects a slight excess of maternally derived rearrangements among the inherited translocations, which is more so within the reciprocal rearrangements (mat/pat = 1.36) than Robertsonian (mat/pat = 1.11). This is also comparable to previous observations.[6,7,13,14] All but one of our reciprocal translocations would be expected to generally segregate 2:2, and the slight skew toward maternal carriers here is very close to that observed by Daniel et al.[17] in relation to unbalanced progeny.

The mutation rate for Robertsonian rearrangements was lower (23% versus 38%) than that observed by Hook et al.,[14] but our rate for reciprocals matched theirs closely (31% versus 29%, respectively).

Follow-up data on balanced translocations found at prenatal diagnosis have been difficult to obtain. The presumption is often made that familial rearrangements should not differ from the general population. Warburton[10] used a collaborative series to evaluate the outcome of cases of de novo structural rearrangements found at amniocenteses. An excess of abnormalities was suggested by Warburton's study but not on the order of magnitude seen in selective population surveys.[3-5] This evaluation was limited by the still relatively small numbers involved and the limited duration of follow-up. An upper limit of risk of 14% for any type of balanced structural rearrangement was suggested by Warburton.[10] We have been able to obtain specific follow-up data on 95% of our de novo balanced translocations, of which nearly one third were ≥3 years old and another one third were ≥6 months old. Combination of our follow-up data with that on translocations only from Warburton's study already cited,[10] a smaller single-center prenatal study,[13] and a consecutive newborn series from Denmark[7] allowed analysis of 158 translocations culled from 93,647 cases (Table III). Only five abnormal outcomes were noted among 80 inherited translocations, and only seven among 80 de novo cases. These rates are not significantly different from one another by χ^2 analysis or from a conservative estimate of the expected frequency of abnormality in the general population of 3% to 4%.

It appears that with careful follow-up the majority of cases of balanced translocations incidentally found at amniocentesis can be determined to be either inherited or de novo. Despite this, delays in the procurement of samples can be as problematic as total nonavailability of samples. To preclude the problems discussed herein, we strongly urge cytogenetic and other genetic screening in proposed anonymous artificial insemination donors.[18]

The pooled data suggest that for known de novo translocations, the risk for abnormal outcome is not significantly greater than that of the inherited group, nor the general population; however, complete long-term developmental follow-up of such cases remains limited. Certainly, the experience with population stud-

ies of the retarded[8-5] suggest caution in counseling of these seemingly nonsignificant risks. It remains possible that some additional biasing factor is responsible for the differences observed, and that a subgroup of prenatally detected cases may have comparable risk levels. After careful ultrasonographic evaluation has proved normal, we recommend that a maximum risk of 10% be used for such cases, and that the risk is roughly one half of that figure for "possibly" de novo cases because of paternal nonavailability. Given the similarity between outcome in inherited and de novo cases we do not recommend further pursuit of possibly false paternity in de novo cases.

We thank the entire staff of The Genetics Institute, its referring physicians, Helen Hamaguchi, RN, Sonia Martinez, MD, and Anita Yousoofian for their assistance in the study and preparation of this manuscript.

Amniotic fluid acetylcholinesterase ratios in prenatal diagnosis of fetal abnormalities

JoAnn C. Kelly, PhD, Elizabeth Petrocik, and E. Robert Wassman, MD
Pasadena, California

This study examined 141 pregnancies with acetylcholinesterase in the amniotic fluid to determine if an acetylcholinesterase/pseudocholinesterase ratio cutoff could be set to distinguish between neural tube defects, ventral wall defects, other fetal defects, and pregnancy problems. Amniotic fluid specimens with positive or faintly positive acetylcholinesterase bands were studied. They were scanned and analyzed for the acetylcholinesterase/pseudocholinesterase ratio. In 62 of 65 fluid samples from open neural tube defects, the acetylcholinesterase/pseudocholinesterase ratios were >0.13. All cases with ventral wall defects (n = 29), fetal blood contamination (n = 16), or fetal ascites (n = 2) had acetylcholinesterase/pseudocholinesterase ratios <0.13. Samples of cystic hygroma fluid (n = 10) had acetylcholinesterase/pseudocholinesterase ratios >0.13. Two patients with fetal teratomas had intermediate values. All patients with normal outcomes but positive acetylcholinesterase had ratios of <0.12. Acetylcholinesterase/pseudocholinesterase ratios are a valuable part of a prenatal program to accurately diagnose fetal abnormalities. (AM J OBSTET GYNECOL 1989;161:703-5.)

Key words: Acetylcholinesterase, AChE, neural tube defects

Gel electrophoresis acetylcholinesterase has proved useful in differentiating false-positive amniotic fluid α-fetoprotein values from those indicating true fetal defects.[1-3] Detection of acetylcholinesterase not only provides biochemical evidence for the presence of a neural tube defect[4] but also reduces the incidence of false-positive diagnoses that are based on α-fetoprotein determinations.[5] The presence of acetylcholinesterase, however, is not specific for neural tube defects. It can be found in the presence of other fetal defects and pregnancy complications, including ventral wall defects and fetal blood contamination.[6, 7] Earlier studies have shown that neural tube defects can usually be distinguished from ventral wall defects by using a densitometric scan ratio of acetylcholinesterase to pseudocholinesterase.[6, 8, 9]

In this study 141 pregnancies with known outcomes and with acetylcholinesterase in the amniotic fluid were examined to determine a cutoff for the acetylcholinesterase/pseudocholinesterase ratio that could distinguish among neural tube defects, ventral wall defects, other fetal defects, and pregnancy problems.

Material and methods

One hundred forty-one amniotic fluid specimens with positive or faintly positive acetylcholinesterase bands were collected between January 1, 1986, and January 1, 1989, and stored at −20° C. They were retrieved from storage, electrophoresed in duplicate a second time, scanned, and analyzed for the acetylcholinesterase/pseudocholinesterase ratio. Ratios reported here were the average of two determinations. The pregnancy outcomes were known in all cases. All samples included in the study had elevated or "high normal" amniotic fluid α-fetoprotein levels of >1.7 multiples of the median. All samples negative for acetylcholinesterase, regardless of α-fetoprotein level, were excluded from the study. Samples obviously contaminated with blood were checked for fetal cells with a modified Kleihauer-Betke stain.[10]

Polyacrylamide slab gel electrophoresis was performed with a minislab gel electrophoresis apparatus.[2, 6, 8] The acetylcholinesterase-specific inhibitor BW284c51 was used to confirm the identity of the diagnostic band. The gels were stained with dithiooxamide to amplify the cholinesterase band densities. The gels were scanned on a Helena Laboratory Cliniscan 2 densitometer. The pseudocholinesterase and acetylcholinesterase bands were denoted as those in positions 1 and 2 by Smith et al.[1]

Results

There were 65 pregnancies in which there was an open neural tube defect in the fetus: 11 with anencephaly, 49 with open spina bifida, and 5 with open encephalocele. Of the 65 open neural tube defect pregnancies, 62 had acetylcholinesterase/pseudocholinesterase ratios >0.13 (see Table I). All three patients with

Table I. Acetylcholinesterase/pseudocholinesterase ratios in amniotic fluid samples

	n	*Acetylcholinesterase/pseudocholinesterase ratio*	
		Mean ± 1 SD	*Range*
Neural tube defect			
Anencephaly	11	0.27 ± 0.11	0.12-0.46
Open spina bifida	49	0.48 ± 0.16	0.11-0.94
Encephalocele	5	0.27 ± 0.15	0.07-0.43
Ventral wall defect			
Gastroschisis	19	0.06 ± 0.02	0.03-0.11
Omphalocele	10	0.06 ± 0.02	0.02-0.09
Cystic hygroma fluid	10	0.34 ± 0.11	0.16-0.49
Fetal ascites	2		0.04, 0.12
Bloody fluid	16	0.05 ± 0.03	0.02-0.08
False positive results	6	0.05 ± 0.04	0.01-0.12

lower acetylcholinesterase/pseudocholinesterase ratios had confirmed open defects (anencephaly, spina bifida, or encephalocele). One additional pregnancy with a membrane-covered spina bifida cystica had a ratio of 0.03. All 29 of the fluids from fetuses with ventral wall defects had acetylcholinesterase/pseudocholinesterase ratios that were <0.11 (Table I).

Twelve pregnancies with abnormal fetal fluid accumulations were studied. The 10 specimens in which fluid was obtained from cystic hygromas had acetylcholinesterase/pseudocholinesterase ratios >0.16 (Table I). Two pregnancies with fetal ascites fluid had relatively low ratios (0.04 and 0.12) in the amniotic fluid.

There were 16 bloody amniotic fluid specimens in which fetal blood cells were identified. All of these samples had acetylcholinesterase/pseudocholinesterase ratios <0.08 (Table I). In addition, there were six samples with acetylcholinesterase present in the amniotic fluid but ultrasonographic examinations, karyotypes, and outcomes were normal. These six cases represent true false-positive results, but in no case was the acetylcholinesterase/pseudocholinesterase ratio >0.12 (Table I).

Twelve other cases of miscellaneous fetal and pregnancy problems also had acetylcholinesterase in the amniotic fluid and were examined for the acetylcholinesterase/pseudocholinesterase ratios (see Table II). Three cases of chromosomal abnormalities were found that had elevated α-fetoprotein levels with acetylcholinesterase in the amniotic fluid. These cases included two of trisomy 13 without scalp defects and one of trisomy 21. There were no open fetal defects observed in these cases. There were five cases involving death of one or more fetuses (Table II). In each of these cases the acetylcholinesterase/pseudocholinesterase ratio was determined. In four of the five cases ratios were in the range seen with neural tube defects; however, the migratory pattern was usually smeared and visibly different. Two cases of fetal teratomas studied had acetylcholinesterase/pseudocholinesterase ratios of 0.18 and 0.08. One case of fetal hydronephrosis had a very light band with a ratio of 0.01. Finally, one case in which the fluid was drawn from a renal cyst had an intermediate acetylcholinesterase/pseudocholinesterase ratio of 0.14.

Table II. Acetylcholinesterase/pseudocholinesterase ratios in amniotic fluid from pregnancies with chromosomal and other fetal problems

Defect	*Acetylcholinesterase/pseudocholinesterase ratio*
Chromosomal abnormality	
Trisomy 13	0.10
Trisomy 13, fetal death	0.02
Trisomy 21	0.08
Fetal death	
1 Fetus of triplets	0.18
Both twins	0.32
Both twins	0.37
After amniocentesis	0.09
1 Fetus of twins	0.27
Teratoma	
Case 1	0.18
Case 2	0.08
Miscellaneous	
Renal cyst fluid	0.14
Fetal hydronephrosis	0.01

Comment

The results from this study confirm and extend earlier reports on the usefulness of acetylcholinesterase electrophoresis as a secondary test in the prenatal diagnosis of neural tube defects and other fetal and pregnancy problems.[1-3] Acetylcholinesterase testing enhances the specificity of prenatal testing for neural tube defects.[4,5] The presence of acetylcholinesterase in the amniotic fluid increases the odds of finding a neural tube defect when the amniotic fluid α-fetoprotein level is elevated. However, positive acetylcholinesterase results have also been noted with ventral wall defects and other conditions.[6,7] Densitometric scanning of acetylcholinesterase electrophoresis gels is useful in the differential diagnosis of fetal defects. In this study we scanned gels of amniotic fluid samples that contained acetylcholinesterase from pregnancies with various problems to determine whether the acetylcholinesterase/pseudocholinesterase ratios would be consistent and useful in the interpretation of the results. Our results in the pregnancies with neural tube defects and ventral wall defects were in accord with those of previous reports.[6,9] In those smaller studies a ratio of 0.15 was used to differentiate neural tube defects and ventral wall defects. In our laboratory we found that a comparable cutoff value of 0.13 gave the most consistent interpretation.

This study also included amniotic fluid from other

fetal and pregnancy conditions. It was determined that fluid from cystic hygromas was similar to fluid from pregnancies with neural tube defects. Fetal ascitic fluid, however, yielded lower ratios. Bloody specimens that contain fetal blood cells can have acetylcholinesterase present in the amniotic fluid and, as such, can yield conflicting results. In this study it was observed that all such bloody fluid samples had ratios lower than those seen with neural tube defects.

Several other conditions yielded positive acetylcholinesterase results. There were three pregnancies with fetal aneuploidy without the presence of neural tube defects that were positive. In each of these cases the acetylcholinesterase/pseudocholinesterase ratio was less than the cutoff of 0.13. The presence of fetal death also can cause positive acetylcholinesterase results. In these cases the gel pattern frequently appears somewhat different, although the scanning results were variable. Fetal teratomas, renal cysts, and hydronephrosis can also cause acetylcholinesterase to be present in the amniotic fluid. Ultrasonographic examination is useful in the interpretation of the results in such cases.

There were six actual false-positive specimens in this study that had elevated α-fetoprotein levels and also were positive for acetylcholinesterase. These six specimens all had ratios that were lower than those seen with neural tube defects. High-resolution ultrasonography is often helpful and should always be offered to patients with elevated amniotic fluid α-fetoprotein levels and positive acetylcholinesterase electrophoresis. Patients with normal ultrasonograms, normal karyotypes, and normal outcomes had ratios of <0.09. Overall, significant exceptions to the findings occurred in <4% of all cases. Acetylcholinesterase/pseudocholinesterase ratios are a valuable part of a prenatal program to accurately diagnose fetal abnormalities.

Effect of diagnostic and therapeutic cordocentesis on maternal serum α-fetoprotein concentration

Carl Weiner, MD,[a] Stanley Grant, RN,[a] Jerry Hudson, PhD,[b] Roger Williamson, MD,[a] and Katharine Wenstrom, MD[a]

Iowa City, Iowa

We investigated the affect of cordocentesis (n = 36) and intravascular transfusion (n = 14) performed with a fixed needle guide on maternal serum α-fetoprotein levels. In 50% of the procedures, the placenta was anterior and punctured. For all patients, maternal serum α-fetoprotein levels rose 70.8% ± 28%. The magnitude of the rise was unrelated to the number of attempts necessary, gestational age, or the initial maternal serum α-fetoprotein levels concentration. The location of the placenta was the sole identified variable related to the rise. A total of 44% of the patients had a significant increase in maternal serum α-fetoprotein level when the placenta was anterior. In contrast, only 4% of the patients had a significant rise in maternal serum α-fetoprotein level when the placenta was other than anterior. There was no difference in the frequency of a significant rise in maternal serum α-fetoprotein level concentration between the patients who underwent cordocentesis and those who underwent intravascular transfusion. On the basis of these findings, we recommend that when maternal isoimmunization is a potential concern and the placenta is anterior, the umbilical cord should be approached either through a window or laterally from the placenta. (AM J OBSTET GYNECOL 1989;161:706-8.)

Key words: α-Fetoprotein, cordocentesis, pregnancy, placenta

Cordocentesis is both safe and efficient in experienced hands.[1, 2] It has become the method of choice to obtain a fetal blood sample. Amniocentesis is associated with a transient increase in maternal serum α-fetoprotein concentration.[3-7] Variables that affect the magnitude of the increase include needle size, the number of punctures necessary, and whether the needle traverses the placenta. It is likely the increase results from the leakage of either fetal blood, plasma, or both into the maternal circulation. One of the major indications for cordocentesis is the diagnosis and treatment of fetal hemolytic disease.[1] It has been opined at several scientific meetings that whereas cordocentesis has the advantage of supplying direct and accurate information compared with amniocentesis, it enhances maternal sensitization more than does amniocentesis. Should this be true, it will affect the indications and methods used for cordocentesis. A randomized trial that compares the efficacy of amniocentesis with cordocentesis for the evaluation of fetal hemolytic disease has not been, and for multiple reasons probably will not be, performed. This investigation has taken a different approach. We sought to determine prospectively the risk of maternal contamination with fetal blood-plasma during or shortly after cordocentesis by measuring the concentration of maternal serum α-fetoprotein.

Material and methods

Fifty consecutive women who underwent either diagnostic (n = 36) or therapeutic (intravascular transfusion, n = 14) cordocentesis for clinical indications were studied. This investigation was approved by the University of Iowa Human Subjects Committee and consent was obtained from each patient.

A specimen of maternal blood was obtained immediately before and 25 to 35 minutes after the procedure. All maternal serum α-fetoprotein measurements were performed by the State of Iowa Hygienics Laboratory, which participates in the Foundation for Blood Research's (Scarborough, Me.) external quality control program. The sample pairs were measured in duplicate by radioimmunassay (Amersham, Arlington Heights, Ill.) during the same run to eliminate interassay variation. Intra-assay variation was <10%.

Our method for cordocentesis has been described in detail elsewhere.[1] All procedures were performed with a 22-gauge spinal needle (Beck-Dickinson, Rutherford, N.J.) and a 5 mHz sector transducer (General Electric 3600, Rancho Mirage, Calif.) with an attached needle

Other	25	8*	4†

*$p = 0.003$.[5]
†$p < 0.05$.[3]

guide (CIVCO, Kalona, Iowa). No attempt was made to avoid the placenta.

Statistical analyses used subroutines from ABstat, rel 5.02 (Anderson-Bell, Parker, Colo.). The combined group and the diagnostic and therapeutic procedures were individually used as data sets. An independent Student *t* test was used to compare ordinal means, χ^2 was used with Yates correction to compare percentages, and linear regression was used to examine the relationship between maternal serum α-fetoprotein and the change in maternal serum α-fetoprotein level, gestational age, and the number of needle insertions. A *p* value ≤0.05 was considered significant.

Results

The planned procedure was successful in all patients and there were no complications. The mean (±SEM) gestational age was 27 weeks' gestation ± 0.7 weeks (range, 19 to 37 weeks). The placenta was located anteriorly in 50% of both diagnostic (18:36) and therapeutic (7:14) procedures. Placental location was unrelated to the number of attempts necessary. The maternal skin was punctured ≤three times in 94% (47:50) of the patients.

The initial maternal serum α-fetoprotein level correlated with gestational age ($r = 0.384, p = 0.006$). Maternal serum α-fetoprotein concentration rose a mean of 70.8% ± 28%, (range, −14.3% to 1058%) after the procedure. The number of attempts necessary to obtain the blood sample was unrelated to the percentage the maternal serum α-fetoprotein level rose. Further, there was no correlation between the percentage the maternal serum α-fetoprotein level rose and either gestational age ($r = 0.18$, $p = 0.22$) or the initial maternal serum α-fetoprotein concentration ($r = 0.08$, $p = 0.56$).

Placental location was the sole identified determinant of the rise. Maternal serum α-fetoprotein concentration rose 133% (52%) when the placenta was anterior (and therefore punctured) compared with 8.6% ± 8% when it was not ($p = 0.02$, two-tailed Student *t* test).

The results were assessed with two previously published criteria[3,5] for a significant rise in maternal serum α-fetoprotein levels after amniocentesis with stratification by placental location (Table I). The percentage of women who had a significant rise was greater when the placenta was anterior with both methods.

The above analyses was repeated when the participants were stratified by the type of procedure (diagnostic or therapeutic). The results were virtually identical and are not shown.

Comment

The number of centers that perform cordocentesis has grown rapidly. Because a major indication for cordocentesis is the diagnosis and treatment of fetal hemolytic disease, concern that cordocentesis might lead to enhanced maternal sensitization is understandable inasmuch as the placenta is often punctured and the needle position is often manipulated when a free-hand technique is used. We have observed the occasional patient who had a marked increase in the indirect Coombs titer after cordocentesis. However, many of these patients have had a history of severely affected offspring or high antibody titer at the outset.

The present study clearly documented a rise in the maternal serum α-fetoprotein concentration after both cordocentesis and intravascular transfusion. It does not address the risk of a "slow leak" nor does it attempt to discern between the leakage of fetal plasma versus whole blood. However, the study convincingly demonstrates that the risk of contamination is limited mostly to those women with an anterior placenta in which placental puncture was routine. With the use of previously published figures[3-7] (with correction for the distribution of placental locations), there is no obvious difference for the risk of a significant rise in maternal serum α-fetoprotein levels between amniocentesis and cordocentesis as performed in our institution with a fixed needle guide. We observed that the number of attempts required to obtain the needed sample was unrelated to the rise in maternal serum α-fetoprotein concentration. This may seem illogical. However, most patients with an anterior placenta required only one attempt. A larger number of patients with an anterior placenta who required multiple attempts might reveal a positive relationship between the number of attempts and the rise in maternal serum α-fetoprotein levels.

Fetal α-fetoprotein concentration declines with advancing gestation. Thus it is possible that a large leak relatively late in gestation might have minimal impact on the maternal serum α-fetoprotein level. A control group of patients who underwent amniocentesis across a range of gestational ages is not feasible in our institution. However, the lack of a correlation between gestational age and the magnitude the maternal serum α-fetoprotein level rose argues against this possibility.

In conclusion, cordocentesis is associated with a significant increase in maternal serum α-fetoprotein levels when the placenta is punctured. On the basis of these findings, we recommend that when maternal isoimmunization is a potential concern and the placenta is anterior, the umbilical cord should be approached either through a window or laterally from the placenta. If the woman has an Rh-negative blood type and is unsensitized, the fetal blood type should be determined. If the fetus has an Rh-positive blood type, anti-D immunoglobulin should be administered, as is the practice for amniocentesis.

Two hundred intrauterine exchange transfusions in severe blood incompatibilities

Marie-Hélène Poissonnier, MD,[a] Yves Brossard, MD,[b] Nicole Demedeiros, MD,[a] Juliana Vassileva, MD, Françoise Parnet, MD,[b] Marc Larsen, MD,[b] Monique Gosset,[b] Jacques Chavinie, MD,[a] and Jacques Huchet, MD[b]

Paris, France

Two hundred intrauterine exchange transfusions were performed under local anesthesia in 107 cases of blood incompatibilities (60 fetuses with severe anemia and 47 with hydrops). Under sonographic guidance, depending on fetal and placental position, an optimal puncturing site was selected along the umbilical vein: placental insertion, fetal insertion, or fetal intraabdominal segment. Tests were immediately performed to confirm fetal origin of blood obtained and estimate hemoglobin level. Blood used for exchange transfusion was compatible with maternal blood and had a hematocrit value of 75%. Exchange transfusion was continued until a hemoglobin level of 16 gm/dl was reached. This procedure was first associated with intraperitoneal transfusions and was subsequently used independently once a month to maintain an adequate hemoglobin level. In 4 fetuses with hydrops, antenatal regression of this sign was observed in 33 cases (70.2%). Overall outcome of 107 fetuses after exchanges was 84 living neonates (78.5%), 15 deaths in utero, and eight neonatal deaths. The survival rate was 91.6% for fetuses without hydrops and 61.7% for those with hydrops. The advantage of exchange transfusion appears to be rapid and efficient correction of anemia with elimination of incompatible fetal red blood cells. (Am J Obstet Gynecol 1989;161:709-13.)

Key words: Hydrops, fetal therapy, intrauterine fetal exchange transfusion, isoimmunization, fetal blood sampling

Severe fetal anemia and fetal hydrops caused by blood incompatibilities are generally associated with poor perinatal outcome, especially if hydropic signs develop during the second trimester. Although intraperitoneal transfusion has been used efficiently to treat fetuses without hydrops, its results for treatment of hydropic fetuses have been disappointing.[1-3] Rodeck et al.[4] reported intravascular transfusions first under fetoscopy and then under sonographic guidance.[6] Others have subsequently used the latter technique successfully.[6-12] More recently, Jacquetin et al.[13] and Grannum et al.[14] have performed intrauterine fetal exchange transfusions.

The purpose of this study was to evaluate the efficiency of intravenous fetal exchange transfusion for severe immunizations.

Material and methods

Patient evaluation. Since 1985, of the severely isoimmunized pregnant patients referred to us from France and other countries, 107 were selected for intravenous fetal exchange transfusion for severe fetal anemia with or without hydrops. At the beginning of the series, only fetuses with hydrops were treated with intravenous fetal exchange transfusion and the others with intraperitoneal transfusion. Starting in August 1987, severe anemia cases were also treated with intravenous fetal exchange transfusion. The fetuses treated had anti-D (level between 12.5 and 150 IU/ml), anti-Kell, or anti-c immunizations.

Intravenous fetal exchange transfusion was chosen after diagnosis of severe fetal hemolysis by either optical density measurements of amniotic fluid at an optical density of 450 nm, hemoglobin level by percutaneous umbilical blood sampling <8 gm/dl, or ultrasound evidence of hydrops (ascites alone or associated with pericardial or pleural effusions, subcutaneous edema, placentomegaly, and hydramnios).

Intrauterine fetal exchange transfusions

Instruments. Intrauterine partial exchange transfusions were carried out under sonographic guidance by means of a 15 cm long, 18- or 19-gauge needle that was introduced through the maternal abdominal wall

and uterus and an 18 cm long, 20- to 22-gauge puncturing needle according to gestational age.

Vena puncture. The intravenous fetal exchange transfusion procedure was performed under local anesthesia in an operating room after sedation of the mother with intramuscular diazepam and atropine. Neither tocolytic agents nor antibiotics were used. An optimal puncturing site along the umbilical vein was chosen. The preferred puncturing site was the placental insertion; when not easily accessible (e.g., when the placenta was posterior behind the fetus), another site was chosen, that is, fetal insertion or fetal intraabdominal segment.

To ensure correct needle location in the fetal vein, we used the following criteria: bright red color characteristic of umbilical venous blood, bevel position under sonograhpic guidance, and scintillating aspect of blood flow.

Fetal origin of blood was immediately checked by a panel of antibodies, including small i. The Kleihauer-Betke test was achieved secondarily. All fetuses were paralyzed with vecuronium bromide (0.1 mg/kg) once intravascular access was achieved.[15]

Transfusion technique. Irradiated O-negative packed erythrocytes with a 75% hematocrit level were used. Withdrawn aliquots were calculated on the basis of 5% of total blood volume, which was considered 16 ml/100 gm of estimated fetal weight. Ten to 20 uninterrupted cycles of injections and withdrawals of 1 to 4 ml were performed, depending on the initial hematocrit value and gestational age. During intravenous fetal exchange transfusion, fetal hematocrit and hemoglobin values were periodically checked. Exchange transfusion was continued until the hemoglobin level reached 16 gm/dl. The oxygenated aspect of withdrawn blood and fetal heart rate monitored under sonography served as criteria of fetal health. Average duration of intravenous fetal exchange transfusion was 45 minutes (range, 30 to 90 minutes). The main difficulty throughout the procedure was to avoid needle displacement. In most cases the umbilical vein had to be punctured two or three times either at the same site or at other sites along the tract. The procedure was discontinued when the desired hemoglobin level was attained, where severe fetal heart rate deceleration occurred, or in rare cases of difficulty in repuncturing the cord. The procedure was similar irrespective of gestational age; however, before 20 weeks it was more delicate to perform because of vein size and fragility. Exchange transfusions were repeated once a week until the hydropic state resolved. Pregnancies were followed by daily fetal heart rate monitoring and weekly sonography. Until August 1987, after hydrops reversal, intraperitoneal transfusions were carried out once a week until delivery. After August 1987, intravenous fetal exchange transfusion was used alone once a month because it appeared to be safe and had a more prolonged effect than did intraperitoneal transfusion.

Criteria for delivery were lung maturity checked by the lecithin/sphingomyelin ratio and if possible gestational age of 35 weeks, except of in cases of earlier complication. This led us to perform intravenous fetal exchange transfusion as late as 33 weeks, since the risks associated with the procedure were less than the risk of premature birth.

Results

From March 1985 to September 1988, 107 patients with severe blood incompatibilities were treated by 200 intravenous fetal exchange transfusions. Forty-seven fetuses showed signs of hydrops, and 60 fetuses had severe anemia without hydrops, that is, hemoglobin ≤8 gm/dl. Hydrops was rarely observed before 20 weeks with hemoglobin levels as low as 2 gm. At a later stage, hydrops was usually found associated with hemoglobin levels between 2 and 8 gm/dl. Patients were immunized against D in 91 cases, c in nine cases, Kell in six cases, and Miltenberger in one case. The first intravenous fetal exchange transfusion was performed between 17 and 32 weeks, with a mean gestational age of 26.7 weeks. Until August 1987 intravenous fetal exchange transfusions (one to seven) were used after the first treatment, and thereafter intravenous fetal exchange transfusion (one to four) were used alone.

Reversal of intrauterine hydrops. At the time of the first intravenous fetal exchange transfusion, 47 fetuses already had severe hydrops. Thirty-three (70.2%) showed evidence of reversal of hydrops after one (22) or two (11) intravenous fetal exchange transfusions. Mean hemoglobin levels before and after intravenous fetal exchange transfusion were 5.6 gm/dl (range, 1.7 to 6.7) and 16.2 gm/dl (range, 9 to 17.4), respectively. Reversal of hydrops was correlated with hemoglobin level.

Fetal death. Of 107 fetuses, there were 15 antenatal deaths, 10 of which were in the hydrops group (mean gestational age 26 weeks; range, 24 to 33) and five in the anemia group (mean gestational age 20.4 weeks; range, 18 to 24). Complications possibly resulting from the technique were one cord hematoma and four premature rupture of membranes, which occurred within a week after the procedure at 20, 23, 32, and 33 weeks of gestation. In nine patients severe hydrops did not resolve despite treatment. In one patient hydrops appeared despite intravenous fetal exchange transfusion (Table I).

Outcome of 47 hydropic fetuses. Thirty-seven fetuses were born alive. Eight died during the first week after birth: five were born hydropic, and two died of prematurity complications after premature rupture of membranes. In one case during intraperitoneal trans-

PROM, Premature rupture of membranes.

fusion, an intraperitoneal hemorrhage was seen under sonography and the infant born at 31 weeks died after intraventricular hemorrhage on the third day. Twenty-nine infants were in good neonatal state with a mean birth weight of 2772 gm (range, 1200 to 3330) at a mean gestational age of 33.8 weeks (range, 28.7 to 36.5). The mean hemoglobin level at birth was 11.9 gm/dl (range, 8.7t o 17.2). Sixteen newborns required no exchange transfusion, eight newborns were given one, and five were given two.

Outcome of 60 nonhydropic fetuses. Five fetuses died in utero, but no neonatal deaths occurred among the 55 newborns. The mean gestational age was 33.7 weeks (range, 30 to 39). At birth the mean weight was 2498 gm (range, 1910 to 3200) and the mean hemoglobin level was 10.7 gm/dl (range, 3.7 to 18.2). Twelve newborns required no exchange transfusion, 24 were given one, and 19 were given two to four. No infant was icteric.

Case reports

Case 1. Mrs. T, Rh-negative, anti-D + Duffy, gravida 8, para 3, had a past history of two spontaneous abortions, one neonatal death, and two in utero deaths of hydropic fetuses at 39 and 23 weeks. She was referred to our institution in 1986 for severe maternal isoimmunization. Ten intraperitoneal transfusions were administered between 20 and 33 weeks of gestation. A healthy infant, weighing 2420 gm, was delivered at 34 weeks. The next pregnancy was treated with intravenous fetal exchange transfusion. The antibody level was 10 μg/ml. Although the hemoglobin level was 3.7 gm/dl at 21 weeks, ultrasound studies revealed that the fetus was not hydropic. The hemoglobin level was 17 gm/dl after the first intravenous fetal exchange transfusion. We performed four other intravenous fetal exchange transfusions at 25, 29, 32, and 34 weeks. The last two intervals were shorter because optimal hemoglobin levels were not reached. The fetus was delivered at 36 weeks and weighed 220 gm. Use of intravenous fetal exchange transfusion enabled us to reduce the number of procedures and obtain better maturity.

Case 2. Mrs. B, Rh-negative, anti-D + C, gravida 4, para 3, had a very high antibody level (52 μg/ml). This patient was referred to us with hydrops at 28 weeks of gestation, and the first intravenous fetal exchange transfusion was performed. The initial hemoglobin level was 7.9 gm/dl, with severe thrombopenia (platelet count 23000/ml). The exchange was discontinued at 16.8 gm/dl. Although the hemoglobin level was corrected, hydrops was not resolved. We performed the second intravenous fetal exchange transfusion at 31 weeks. The hemoglobin level was 9 gm/dl at the beginning of 16.10 gm/dl at the end of the procedure, and there was still severe thrombopenia. The fetus died shortly after the intravenous fetal exchange transfusion. Its weight was 2900 gm with hydrops. The placenta weighed 1490 gm.

Case 3. Mrs. L, Rh-negative, anti-D + C, gravida 7, para 6, had a past history of three children and two antenatal deaths at 32 and 24 weeks' gestation. During the index pregnancy, the fetus showed signs of severe hydrops at 21 weeks with peritoneal, pericardial, and pleural effusions. Hemoglobin level was 1.4 gm/dl. There was no thrombopenia or hypoxia. Intravenous fetal exchange transfusion was started with aliquots of 1 ml. At the end of exchange transfusion, the hemoglobin level was 15.7 gm. Hydrops was resolved after 48 hours. Three other intravenous fetal exchange transfusions were performed at 23, 29, and 33 weeks. At 36 weeks a healthy newborn weighing 3000 gm was delivered by cesarean section.

Comment

The three therapeutic procedures currently used for severe isoimmunizations, namely, intraperitoneal, intravascular, and intravascular exchange transfusions, are compared.

Intraperitoneal in utero transfusion has been found to be effective in cases of fetal anemia without hydrops.[3] In hydropic cases, a poor survival rate (28.5%) is reported by Frigoletto et al.[3] The good results (75%) of Harmann et al.[2] are an exception. Because anemia was only partially corrected, it was necessary in most cases to repeat the procedure once a week.[6] Between 1977 and 1986, we treated 228 cases of severe isoimmunizations with 901 intraperitoneal transfusions. An average of 3.9 intrauterine transfusions were performed, with a 76.3% survival rate. For hydrops appearing before 28 weeks, the rate was 24% (unpublished data).

Table II. Comparison of survival rates after straight intravascular transfusions in six studies

	No. of cases	*Overall survival (%)*	*Survival of hydrops (N)*
Rodeck et al.[5]	19	84	11/13
De Crespigny et al.[7]	4	75	1/1
Grannum et al.[14]	26	82	16/20
Berkowitz et al.[19]	16	76	—
Brass et al.[12]	23	85.7	5/6
Mackenzie et al.[18]	10	10	—

Intravascular transfusion. Percutaneous intravascular access to the fetus was first attempted by Daffos et al.[15, 16] in 1983 with a fetal death rate of 1.1%. Rodeck et al.[4] described intravascular transfusion under fetoscopy. Rodeck et al.[5] and others[7, 11, 12, 14] also described percutaneous intravascular transfusion under sonographic guidance. The survival rate was between 10% and 85.7%. Good results were obtained in hydropic cases (Table II).

Intravascular transfusion has the benefit of correcting fetal anemia rapidly.[7, 15, 17] However, large quantities of blood must be transfused, and consequently, cardiovascular decompensation might possibly occur in hydropic fetuses. On the other hand, where simple transfusion is used, there is no purge of incompatible fetal erythrocytes and therefore these can be hemolyzed.

Intrauterine exchange transfusion. Overall survival rates for intravascular and exchange transfusions appear to be similar (84% for Rodeck et al. and 75% for Grannum et al.). However, intravenous fetal exchange transfusion may have some of the following advantages: (1) The theoretic risk of cardiac decompensation in severe hydropic cases might be reduced.[18] (2) The interval between procedures is longer (4 weeks except in rare cases in which the desired hemoglobin level of 16 gm/dl is not obtained). (3) This longer interval is made possible by the slow decrease of the hemoglobin level (2 gm 1 wk) compared with the rate of hematocrit decrease of 1 point per day in the study of Rodeck et al.[5] of simple transfusions. (4) Blood removal during exchange transfusion allows the hemoglobin level to be controlled periodically, giving more accurate indications of the blood volume to be exchanged. (5) Therefore it is unnecessary to calculate as Rodeck et al.[4] suggested the blood volume to be transfused. (6) The bright red color of the oxygenated blood removed gives further indication of fetal health. (7) In most cases, intravenous fetal exchange transfusion enabled delivery to be delayed until fetal maturity. (8) Possibly because of complete clearance of incompatible red cells and anemia correction, only a few newborns required exchange transfusions during the neonatal period. We also observed that persistence of hydrops was very rare in newborns, and complications caused by this state during the neonatal period were reduced.

However, exchange transfusion has some disadvantages compared with intravascular transfusion: the procedure is longer, and in theory the risk of infection is increased. There is also an increased risk of accidental needle displacement from the vessel, even when care is used to reduce fetal movements. This risk may be reduced by the introduction of a catheter, as described by Jacquetin et al.[13] in the anterior placenta.

From our study, we made the following observations regarding prognostic factors: (1) Hydrops per se as revealed by sonography is a well-known criterion of poor prognosis. (2) For nonhydropic fetuses, the hemoglobin level is much more accurate for prognosis than the bilirubin level in the amniotic fluid. (3) In hydropic cases thrombocytopenia and a high transaminase level are signs of poor prognosis regarding reversal of hydrops, even if anemia can be corrected. However, we found no significant decrease in platelet counts despite the removal of clotting factors during the exchange transfusion. Berkowitz et al.[19] have suggested another criterion for prognosis, namely, protein level in fetal blood.

In conclusion, intravenous fetal exchange transfusion appears to be safe procedure if performed by a multidisciplinary team with experience in ultrasound-guided invasive fetal procedures. It enables anemia to be corrected efficiently, a large proportion of cases of hydrops to be reversed, and in most cases leads to delivery of a mature healthy newborn requiring minimal treatment during the neonatal period.

Normal values for human umbilical venous and amniotic fluid pressures and their alteration by fetal disease

Carl P. Weiner, MD, Joni Heilskov, RN, Gay Pelzer, RN, Stanley Grant, RN, Katharine Wenstrom, MD, and Roger A. Williamson, MD

Iowa City, Iowa

Umbilical venous and amniotic fluid pressures were measured in 68 human pregnancies at the time that cordocentesis was performed. Normal umbilical venous pressure was unrelated to gestational age and remained within a tight range (5.3 ± 2.3 mm Hg, mean ± SD). Fetuses with an elevated umbilical venous pressure had disorders consistent with either hepatomegaly or congestive heart failure. Umbilical venous pressure was significantly increased before treatment in two fetuses with immune hydrops; it rapidly declined with treatment. Neither gestational age nor umbilical venous pressure was significantly different in the groups that received and did not receive pancuronium. There was a strong relationship between amniotic fluid pressure and gestational age in normal pregnancy ($r = 0.54$, $p < 0.0001$). Women with hydramnios had amniotc fluid pressures greater than control subjects ($p = 0.0007$). This investigation documents normal human amniotic fluid and fetal umbilical venous pressures. These measurements are altered by disease and may prove to be of diagnostic and therapeutic value in the future. (Am J Obstet Gynecol 1989;161:714-7.)

Key words: Fetus, cordocentesis, amniotic fluid pressure, umbilical venous pressure, hydrops fetalis

The development of cordocentesis has greatly simplified access to the circulation of the human fetus. The umbilical vein is the vessel that is most commonly punctured.[1] Umbilical venous pressure should approximate the central venous pressure as much as pressure in the fetal inferior vena cava. Because of the parallel fetal circultory system and the preferential streaming of umbilical venous blood to the left atrium,[2] umbilical venous pressure measurements may even be more sensitive to left ventricular abnormalities than the inferior vena cava. Neither umbilical venous pressure nor amniotic fluid pressure appears to have been systematically investigated throughout pregnancy. To our knowledge, prior studies of amniotic fluid pressure have focused on uterine activity and have not compared resting tone across a wide range in gestation. We hypothesized that human fetal pathologic conditions could alter umbilical venous pressure and amniotic fluid pressure. The purpose of this investigation was to prospectively test this hypothesis by measuring umbilical venous pressure and amniotic fluid pressure in fetuses undergoing diagnostic cordocentesis for a variety of clinical indications.

Material and methods

Sixty-eight cordocenteses were performed for a variety of indications (Table I). Eight fetuses had nonimmune hydrops fetalis and two had immune hydrops fetalis. Our method for cordocentesis has been described previously.[1] Each procedure used a 22-gauge spinal needle and a 5 mHz sector transducer (General Electric 3600, Rancho Mirage, Ga.) with an attached needle guide (Civco, Kalona, Iowa). Neuromuscular blockade was produced with pancuronium (0.3 mg/kg of estimated fetal weight intravenously) when deemed necessary by the operator. After the indicated blood specimen had been obtained, the needle was connected to a tube filled with saline solution that was attached to a solid state pressure transducer (Sorenson Transpac II, #46862-04, supplied by Abbott Critical Care Systems, North Chicago) and pressure monitor (Hewlett-Packard #78833B, Houston). The transducer was meticulously placed at the level of the fetal heart as determined during the preceding ultrasonographic examination. The needle was purged and the pressure read at its nadir. The identity of the vessel punctured was confirmed as the umbilical vein by both observing the flow direction of the injected saline solution and the lack of a pulsatile pressure waveform on the pressure monitor screen. The needle was then withdrawn

*Some subjects had more than one indication.

from the vein into the amniotic cavity. After a brief purge, the nadir pressure was recorded. The time required to obtain both umbilical venous and amniotic fluid pressures was approximately 30 seconds. There was no maternal perception or ultrasonographic evidence of uterine activity during the time the final pressure measurements were recorded. The observation that the nadir pressure was stable also decreased the likelihood of unrecognized uterine activity. The reported umbilical venous pressure reflects subtraction of the amniotic fluid pressure from the measured umbilical venous pressure.

A complete blood count and respiratory blood gas measurements were performed on all fetal blood samples. The complete blood count was performed on blood anticoagulated with 1% ethylenediaminetetraacetic acid on a Technicon H-1 analyzer (Tarreytown, N.Y.). Respiratory blood gas measurements were performed on blood anticoagulated with heparin on automated equipment (Instrumentation Laboratory Blood Gas Manager model 1312, Lexington, Mass.) The pH, P_{CO_2}, and P_{O_2} were measured directly. The base excess, bicarbonate, and oxygen saturation were calculated with standard nomograms.

The group of fetuses termed "control" was comprised predominantly of subjects evaluated for hemolytic disease who ultimately were shown to be either unaffected or to have a normal hematocrit and reticulocyte count. The cause of fetal hydrops was listed when known. Oligohydramnios was considered present when the largest amniotic fluid pocket was <2 cm in all dimensions. The diagnosis of hydramnios required a gross increase in amniotic fluid associated with a size greater than dates–fundal height discrepancy and was made before the pressure measurement.

The results were presented as the mean ± 1 SD. Analyses used subroutines from ABstat rel. 5.10 software (Anderson-Bell, Parker, Colo.) and included least-squares multiple linear regression and independent *t* tests.

Results

The mean gestational age of the fetuses studied was 28.2 ± 5 weeks (range, 19 to 39). Both the amniotic

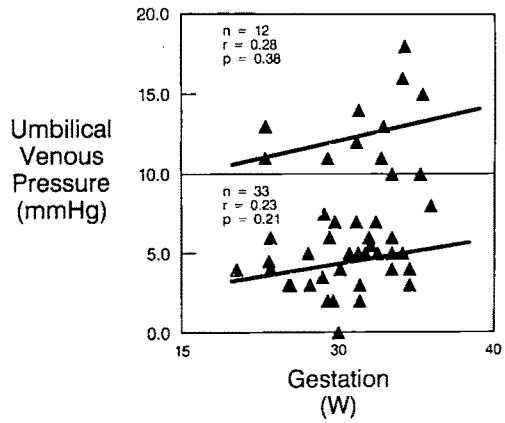

Fig. 1. Scattergram of the 45 fetuses in whom umbilical venous and amniotic fluid pressure was measured. Two distinct populations are obvious. (n = 12 refers to those fetuses with a umbilical venous pressure >2 SD above the norm; n = 33 refers to all others.)

fluid pressure and the umbilical venous pressure measurements were available from 45 subjects. Regression analysis with umbilical venous pressure used as the dependent variable suggested a weak positive relationship with gestational age ($r = 0.28, p = 0.07$). However, this was artifactual. Examination of the scattergram revealed two clear populations of similar gestational age—one whose umbilical venous pressure was <10 mm Hg and one whose umbilical venous pressure was >10 mm Hg (Fig. 1). Of the 14 fetuses assigned to the control group (mean gestational age, 27.4 ± 3 weeks), the mean umbilical venous pressure was 5.3 ± 2.3 mm Hg (range, 2 to 11). There was no relationship between gestational age and umbilical venous pressure in this group ($r = 0.30, p = 0.29$) nor a group made up of all fetuses whose umbilical venous pressure was within 2 SD of the norm.

Each fetus with an umbilical venous pressure >10 mm Hg had a disorder consistent with either congestive heart failure or hepatomegaly, except one fetus with a neural tube defect (Table II). Elevated pressures considered to be consistent with hepatomegaly were observed in two fetuses with hemolytic disease in need of transfusion and two fetuses who had previously been transfused but who had not yet demonstrated complete suppression of erythropoiesis. The two fetuses studied with immune fetal hydrops had an elevated umbilical venous pressure. In each instance the umbilical venous pressure declined rapidly to a normal level during or after intravascular transfusion. An example is shown in Fig. 2. One fetus with a massive cervical teratoma initially had a normal umbilical venous pressure that rose with the development of hydrops. In another fetus with anasarca associated with an asymmetric bilateral chylothorax, the fetal heart was compressed snugly

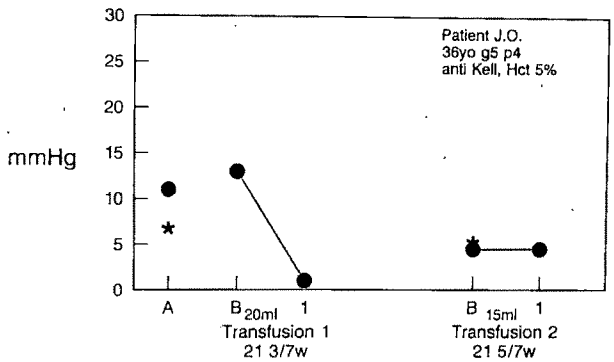

Fig. 2. Umbilical venous pressure *(UVP)* was initially elevated in fetuses with immune hydrops. It declined into the normal range during transfusion. *Asterisk,* Amniotic fluid prssure. *Closed circle* signifies the corrected umbilical venous pressure at each sampling point. The second transfusion occurred 48 hours after the first.

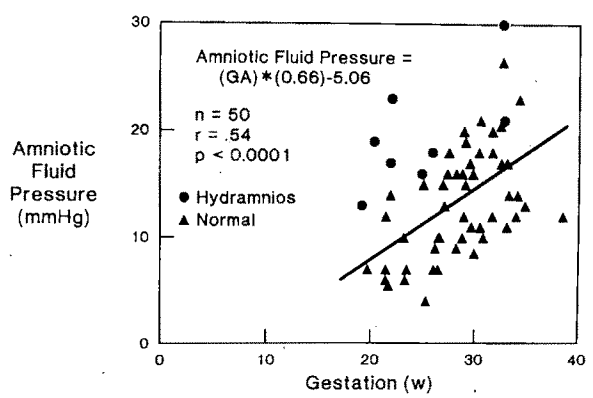

Fig. 3. Amniotic fluid pressure tone rose progressively as gestational age increased. Women with hydramnios had increased amniotic fluid pressure. Pregnancies complicated by anhydramnios (n = 10) excluded.

along the left side of the chest wall. The umbilical artery blood pressure was 18/4 torr. This pressure measurement contrasts markedly with the only other fetuses whose umbilical artery pressure was measured (n = 3): 63/40, 31/26, and 39/19 mm Hg. Bilateral thoracoamniotic shunts were placed, and the hydrops resolved rapidly after the heart returned to its normal position.

Forty of the 45 fetuses (89%) received pancuronium. The gestational age and umbilical venous pressure measurements were not significantly different in the group that received pancuronium compared with the group that did not receive pancuronium.

The mean amniotic fluid pressure for all subjects was 11.8 ± 4 mm Hg. There was a positive relationship between amniotic fluid pressure and gestational age (r = 0.44, p = 0.0006). This relationship increased further when patients with either hydramnios or oligohydramnios were eliminated from the data set

*≥10 mm Hg.

(r = 0.54; p < 0.0001; Fig. 3). Women with obvious hydramnios (n = 8) had a mean amniotic fluid pressure significantly greater than the other patients (19 ± 5 vs. 13.3 ± 5 mm Hg, p = 0.0007) despite being slightly earlier in gestation (27.1 ± 6 vs. 28.6 ± 4 weeks, p = 0.36). In the absence of hydrops and associated hydramnios, there was no obvious relationship between umbilical venous pressure and amniotic fluid pressure.

Comment

This study of 68 pregnancies with various pathologic conditions over a wide gestational age range offers new information concerning human fetal physiology and pathophysiology. It appears to be the first systematic investigation of human amniotic fluid and fetal umbilical cord blood pressure. Each was altered in association with fetal disease.

Blood returning from the placenta courses through the large-bore ductus venosus into the inferior vena cava where it streams preferentially through the foramen ovale into the left atrium.[2] We assume that the umbilical venous pressure is an approximation of the central venous pressure and may also be sensitive to left-sided cardiac alterations. Certainly, additional animal study of factors that alter the umbilical venous pressure is desirable, but at this time our current observations support the above assumptions. Umbilical venous pressure remained within a fairly narrow range throughout gestation but rose in association with disorders likely to produce congestive heart failure or hepatomegaly. The development of hydrops, presumably as a result of high-output failure, in the fetus with a massive cervical teratoma was associated with an increase of the umbilical venous pressure into the abnormal range. The fetus with hydrops associated with

asymmetric chylothorax and a markedly displaced heart had an umbilical artery pressure of 18/4 mm Hg. We believe that this pressure is very low and consistent with some form of cardiac tamponade manifested as decreased cardiac return. Both fetuses with immune hydrops had markedly elevated umbilical venous pressure that returned to the normal range after intravascular transfusion. Although the initial elevation might partially reflect portal hypertension as a result of massive hepatomegaly,[3] the rapid return of the pressure to a normal range suggests that the high umbilical venous pressure is in part explained by myocardial dysfunction (e.g., high-output heart failure), which is quickly alleviated by intravascular transfusion. This conclusion would seem to conflict with studies of the neonate.[4] However, the neonatal studies would be subject to a wide range of variables altered by the birth process. The decline is probably not the result of a cord "spasm" since the umbilical artery systolic/diastolic ratio declined with transfusion. Furthermore, since the completion of this study we have observed the umbilical venous pressure of a fetus with a procedure-related bradycardia; it exceeded 60 mm Hg. A definitive answer will require additional study including fetal blood volume measurement.

Although the number of fetuses who did not receive pancuronium was small, there was no evidence that pancuronium altered the umbilical venous pressure. This is consistent with the known pharmacology because pancuronium causes little or no histamine release and no ganglionic blockade.[5]

The methods used for pressure measurement merit further comment. The fetal pressure transducer is traditionally placed at the level of the maternal heart during animal study. We selected the level of the fetal heart as our standard location because the fetus was the object of the study and the level of the fetal heart can be accurately identified ultrasonographically. It is possible that some fetal trunk rotation occurred from the time the transducer was set and zeroed until the time the pressures were actually measured (1 to 5 minutes). However, we were unaware of any such movement, and fetal movement during the measurement was often inhibited by neuromuscular blockade. Ideally amniotic fluid pressure measurement would occur with the transducer at the level of the needle tip. Therefore the actual amniotic fluid pressure reported in this study may be slightly elevated. However, we do not believe this possible bias is clinically relevant.

The progressive increase in amniotic fluid pressure with advancing gestation was unexpected, although in retrospect it was logical. Prior animal and human studies involving amniotic fluid pressure measurement may have occurred over too narrow a gestational age span or were focused on other areas such as uterine activity or fetal blood pressures. That women with hydramnios have elevated amniotic fluid pressure may relate to our unpublished observation that uterine decompression enhances the efficacy of tocolysis in women with hydramnios and preterm labor.

In conclusion, human amniotic fluid and fetal umbilical pressures may be measured during cordocentesis. These measurements are affected by a variety of fetal disorders. In the future, fetal umbilical pressure measurement may prove of diagnostic and therapeutic value.

Ovine fetal cardiorespiratory response to nicardipine

R. Harold Holbrook, Jr., MD,* Ellen M. Voss, BS, and Ronald N. Gibson, BS
Stanford, California

Nicardipine, a calcium antagonist associated with decreased uterine blood flow in near-term pregnant rabbits and fetal asphyxia after maternal administration in the rhesus monkey and sheep, was infused directly to the fetus in six chronically prepared pregnant ewes at 128 days' gestation. Changes in fetal mean arterial and diastolic blood pressure levels at 2 and 30 minutes after bolus injection of 50 μg were minimal; by 60 minutes these values had returned to preinfusion levels. No significant changes were observed after infusion of 100 μg of nicardipine. Fetal heart rate, fetal arterial blood gas values, and maternal cardiovascular variables did not change at either dose. Fetal plasma concentrations of nicardipine were 78 ± 28 ng/ml and 114 ± 48 ng/ml at 30 minutes after infusion of 50 μg and 100 μg, respectively, well within the range previously reported to be associated with fetal asphyxia. These data suggest that the previously reported fetal acidosis from maternal infusion of nicardipine may be primarily due to a decrease in maternal uterine blood flow rather than a direct fetal effect of the drug. (Am J Obstet Gynecol 1989;161:718-21.)

Key words: Premature labor, calcium channel blockers, nicardipine, fetus, sheep

Calcium antagonists are potential alternatives to 3-adrenergic agonists for preterm labor tocolysis. Nicardipine, a dihydropyridine derivative, has been found to inhibit uterine activity in the preterm pregnant rabbit,[1-3] the rhesus monkey,[4] and the postpartum rabbit.[5] Nicardipine also decreases contractility in isolated human myometrial strips[6] and delays delivery in pregnant rabbits.[5] Nifedipine, a similar dihydropyridine calcium antagonist, has been used as a tocolytic agent in human subjects, but maternal and fetal side effects have not been well studied. Maternally administered nicardipine, however, has been associated with fetal asphyxia in pregnant animals, and placental transfer has been documented. It is not clear whether fetal asphyxia is mediated through alteration in uteroplacental perfusion or by a direct action on the fetus (e.g., alterations in umbilical or ductal blood flow). To determine the effect of nicardipine on the fetus independent of changes in uterine blood flow, we administered the drug directly to the fetus and measured the fetal cardiorespiratory response.

Material and methods

Animal preparations and studies were performed in the Stanford Research Animal Facility. The study protocol was approved by the Stanford University Administrative Panel on Laboratory Animal Care. Six crossbred Western pregnant ewes at 128 days' gestation with single fetuses were fasted 24 hours before surgery and regional anesthesia was induced in the lower body with an epidural injection of 40 mg of tetracaine hydrochloride. Intravenous ketamine hydrochloride (8 mg/min) was administered to maintain sedation, and supplemental diazepam was given as needed up to a total dose of 2 mg/kg. Polyvinyl catheters (0.05 inch inner diameter, 0.09 inch outer diameter) were advanced into the ewe's descending aorta and inferior vena cava through the saphenous artery and vein. A midline abdominal incision was made to expose the uterus. Lidocaine 0.5% was used to induce local anesthesia in the fetus and polyvinyl catheters (0.03 inch inner diameter, 0.05 inch outer diameter) were placed in the fetal descending aorta and inferior vena cava through the saphenous artery and vein. A catheter was placed in the amniotic cavity for measurement of intrauterine pressure. All catheters were filled with sodium heparin, sealed with copper plugs, and tunneled to a pouch attached to the ewe's flank. The ewe received 40,000 U/kg of penicillin postoperatively and was allowed to recover for 48 hours.

With the ewe standing quietly in a study cage with free access to food and water, baseline measurements were made over a 10-minute period. Fetal arterial pressures and heart rate, maternal arterial pressures and heart rate, and amniotic pressure levels were measured on a Gould 2800S 8-channel recorder. Fetal descending aortic oxygen saturation and hemoglobin levels were measured with a Radiometer OSM3 hemoximeter, and blood gases were measured with a Corning 170 blood gas analyzer at 39° C. After baseline measurements

were obtained, a 50 μg bolus of nicardipine hydrochloride (Syntex Pharmaceuticals, Palo Alto, Calif.), prepared as a fresh sterile solution of 2 mg/cc with 6 mg/cc sodium chloride added, was infused into the fetal inferior vena cava. The above measurements were then repeated at 2, 30, and 60 minutes. The animal was allowed to recover for at least 4 hours before baseline measurements were repeated. The study was repeated as above with 100 μg bolus of nicardipine. At 30 minutes after each bolus injection of nicardipine, fetal blood was drawn from the inferior vena cava and centrifuged. The serum was stored frozen at −80° C for later analysis by high-performance liquid chromatography. Nicardipine dosages were chosen on the basis of estimated fetoplacental blood volume to achieve a fetal plasma concentration of approximately 50 ng/ml at 60 minutes. This concentration is similar to that reported in studies in which fetal asphyxia developed after maternal administration.

The ewe was killed by injection of pentobarbital and saturated potassium chloride before bilateral thoracotomy. The fetus was removed from the uterus and weighed. Fetal arterial pressure was corrected by subtraction of the amniotic fluid pressure. Fetal and maternal blood pressure levels and heart rates, and fetal descending aortic blood gas and pH levels were compared before and at each time period after each nicardipine infusion by one-way analysis of variance for repeated measures. When the repeated measures analysis of variance revealed differences between time periods, Fisher's nonparametric paired least significant difference test was used to determine between which measurements the differences were significant.

Results

Fetal arterial pressure level and heart rate, descending aortic hemoglobin concentration, hemoglobin saturation, and blood gas and pH levels were measured in six animals after infusion of 50 μg of nicardipine. In five of these animals, maternal arterial pressure levels and heart rates were also obtained. Values of these variables at preinfusion and at 2, 30, and 60 minutes are listed in Table I. A small (2 to 4 mm Hg) but significant decline in fetal mean and diastolic pressure was noted at 2 and 30 minutes after infusion, but these values returned to baseline by 60 minutes. Changes in all other maternal and fetal variables were not significantly different from preinfusion values at any of the time periods.

Similar results were obtained after infusion of 100 μg of nicardipine. Maternal and fetal variables were measured in five animals and are listed in Table II. No differences in any of the variables were noted at 2, 30, or 60 minutes after infusion.

Fetal plasma concentrations of nicardipine after bolus administration of 50 μg were 527 ± 345 ng/ml, 78 ± 28 ng/ml, and 41 ± 25 ng/ml at 2, 30, and 60 minutes, respectively. With bolus administration of 100 μg of nicardipine, the fetal plasma concentrations were 414 ± 17 ng/ml, 114 ± 48 ng/ml, and 61 ± 29 ng/ml at 2, 30, and 60 minutes, respectively. The calculated half-life for nicardipine in the fetal circulation was 25.6 ± 5.2 minutes and 22.3 ± 5.9 minutes for bolus administration of 50 μg and 100 μg of nicardipine, respectively.

Comment

This study suggests that the previously reported fetal acidosis that occurs after maternal infusion of nicardipine[4] may be primarily due to a decrease in maternal uterine blood flow rather than a direct fetal effect of the drug. The fall in uterine blood flow observed in near-term pregnant animals after maternal infusion of calcium antagonists has been considered to be mainly due to peripheral vasodilation, which results in mater-

nal hypotension and a fall in perfusion pressure. The uterine vasculature is considered to be maximally dilated near term and a diversion of flow to other regions should be expected to occur.

In the pregnant ewe, Golichowski et al.[7] and Harake et al.[8] observed that continuous maternal nifedipine infusion caused a significant fall in maternal arterial pressure levels and a (presumably reflex) rise in maternal heart rate. In Harake's study, a significant fall in uterine blood flow was observed at an infusion rate of 10 μg/kg/min, and fetal pH, arterial oxygen content, and hemoglobin saturation declined significantly. Uterine vascular resistance did not change, however, and therefore the fall in uterine blood flow could be attributed to decreased maternal arterial pressure levels. There was no change in fetal heart rate or arterial blood pressure level. There was, however, an increase in total and regional fetal cerebral blood flow consistent with fetal adaptation to asphyxia.

In the near-term pregnant rabbit,[1-3] continuous maternal nicardipine infusion at dosages that caused significant reductions in prematurely induced uterine activity were found to cause a rise in maternal heart rate and fall in maternal arterial pressure level. A fall in total uterine and placental blood flow also occurred despite a significant increase in maternal cardiac output.[2]

Ducsay et al.[4] administered a bolus of 500 μg of nicardipine to the pregnant rhesus monkey and then continuously infused 6 μg/kg/min. A significant decline in maternal arterial pressure level and increase in maternal heart rate occurred. Despite fetal plasma concentrations of nicardipine, which averaged 6% of maternal serum levels, no changes occurred in fetal heart rate or arterial blood pressure level. There was however, a significant fall in fetal arterial pH and P_{O_2}, and an increase in fetal arterial P_{CO_2}. Uterine blood flow was not measured, but the lack of change in fetal blood pressure level suggests that the fetal asphyxia was more likely a result of a decrease in uteroplacental perfusion.

In our study, bolus administration of nicardipine to the fetus resulted in fetal serum concentrations of 414 ± 17 ng/ml to 527 ± 345 ng/ml after 2 minutes, and 41 ± 25 ng/ml to 61 ± 29 ng/ml at 60 minutes after infusion. The observation that 2-minute serum levels were higher after injection of 50 μg than they were after 100 μg may be explained by an increased variability of serum levels measured soon after injection, before equilibrium is complete. The levels at 30 and 60 minutes, however, reflect the dosage injected, higher levels being associated with the injection of 100 μg. In the rhesus monkey, Ducsay et al.[4] observed fetal asphyxia at peak fetal plasma nicardipine concentrations of 7 to 35 ng/ml. Harake et al.[8] described significant asphyxial changes at fetal plasma nifedipine levels of 91 ± 8 ng/ml. Thus, it would appear that maternal administration of these agents, which results in maternal hypotension and decreased uterine blood flow, is required for these adverse fetal effects to occur.

Because calcium antagonists apparently cross the primate placenta and are vasodilators, the chronically asphyxiated fetus may be adversely affected by these agents. Redistribution of blood flow to vital organs such as the brain, heart, and adrenals through a selective peripheral vasoconstriction may be reversed by vasodilators and result in worsening of fetal asphyxia. Whereas our study did not demonstrate a significant change in fetal peripheral resistance after nicardipine infusion in the normoxic fetus, the effect of this and similar agents on the compensated asphyxiated fetus is not known.

When comparison is made of the side effects of ni-

cardipine and nifedipine, it should be recognized that different calcium antagonists display different degrees of action on uterine, vascular, and cardiac tissue.[9] In addition, calcium antagonists affect fetal and adult cardiovascular systems differently and therefore the typical adult response should not necessarily be expected in the fetus.[10]

Whereas our study confirms the tolerance of the normoxic ovine fetus to nicardipine, the reported adverse effects on uterine blood flow and limited experience with these agents in the treatment of human preterm labor limits enthusiasm for their unrestricted use. Ulmsten et al.[11] have reported that when nifedipine was used clinically to treat premature labor, maternal arterial pressure was not affected, but a transient increase in heart rate occurred. No change in fetal heart rate was observed, and there were no neonatal complications noted. However, Read and Wellby[12] found that although neither maternal heart rate nor blood pressure levels were altered by maternal administration of nifedipine, fetal heart rate was significantly increased. We (Ferguson JE II, Holbrook RH Jr., Unpublished observations) noted decreased diastolic and mean blood pressure and reflex tachycardia in 12 preterm labor patients treated with sublingual and oral nifedipine. Whereas no adverse fetal effects have been reported in human beings, maternal hypotension does occur, and there exists the potential for adverse fetal effects at higher dosages or when fetal growth retardation or chronic asphyxia are present. Further studies of the response to the hypoxic fetus to calcium antagonists and changes in uterine blood flow in human beings are warranted.

Effect of prolonged hypoxemia on fetal heart rate accelerations and decelerations in sheep

Alan D. Bocking, MD,* Susan White, BSc, Robert Gagnon, MD, and Howard Hansford
London, Ontario, Canada

Experiments were conducted in 10 chronically catheterized fetal sheep to determine the effect of 24 hours of hypoxemia in the absence of progressive acidemia on fetal heart rate accelerations and decelerations. Fetal hypoxemia was produced by mechanically restricting uterine blood flow with a vascular clamp placed around the maternal common internal iliac artery. Fetal arterial oxygen tension decreased from 22.3 ± 1.8 to 17.8 ± 1.5 mm Hg at 2 hours and remained low for the 24-hour experimental period. Fetal pH decreased from 7.34 ± 0.01 to 7.20 ± 0.05 at 2 hours and returned to normal values by 12 hours. No significant change was observed in the number or characteristics of fetal heart rate accelerations or decelerations during the 24-hour control period. There was a significant increase in the number of accelerations from 48 ± 4 to 63 ± 4 per hour at 8 hours of hypoxemia followed by a return to control values by 12 hours. There was no significant change in the mean amplitude or duration of accelerations. There was a significant increase in the number of decelerations per hour with an associated increase in the mean amplitude but a decrease in the mean duration of decelerations during the first 16 hours of hypoxemia. We conclude that prolonged hypoxemia in fetal sheep leads to an initial increase in the number of both accelerations and decelerations in fetal heart rate followed by a return to normal patterns indistinguishable from those of the normoexemic fetus. (Am J Obstet Gynecol 1989;161:722-7.)

Key words: Hypoxemia, fetal heart rate, fetal sheep

Assessment of the presence or absence of fetal heart rate (FHR) accelerations in the antepartum period is widely used clinically to determine fetal health.[1] In the near-term human fetus, FHR accelerations occur episodically[2] and generally in association with gross fetal body movements.[3-5] We have shown that in fetal sheep, during the latter third of pregnancy, the majority of FHR accelerations also occur in association with fetal skeletal muscle activity measured by means of electromyogram recordings.[6] It is likely therefore that the central mechanisms controlling FHR accelerations in sheep are similar to that in the human fetus.

Little is known, however, about the mechanisms that regulate accelerations and decelerations in FHR under conditions of prolonged hypoxemia that may occur in human pregnancies, during labor, or in the antepartum period. We have previously demonstrated that there is an increase in both the number and the amplitude of FHR decelerations but no change in the number or characteristics of accelerations in fetal sheep subjected to a 2-hour episode of hypoxemia that is secondary to the restriction of uterine blood flow.[7] We have now extended the period of restricted uterine blood flow to 24 hours to determine if more prolonged hypoxemia in the absence of progressive acidemia will have a different effect on FHR accelerations and decelerations in the fetal sheep. This unique experimental situation would most closely resemble that occurring in human pregnancy with prolonged uteroplacental insufficiency such as may occur with abruptio placentae during the antepartum or intrapartum period.

Material and methods

Surgical procedure. Surgery was performed on 10 pregnant sheep of known mating dates between 120 and 125 days' gestation, with a mean (±SEM) gestational age at the time of surgery of 122 ± 1 days. Anesthesia was induced with intravenous thiopental (Abbott Laboratories, Montreal) and maintained with a combination of 1% halothane and 50% oxygen–50% nitrous oxide. With a sterile technique, a midline incision was made in the ewe's abdomen and a polytetrafluoroethylene vascular clamp was placed around the maternal common internal iliac artery. The ovarian arteries were ligated bilaterally. Polyvinyl catheters (V4; Bolab, Lake Havasu City, Ariz.) were placed in the fetal descending aorta (n = 2) and in the brachiocephalic artery (n = 8) for arterial blood sampling. Polyvinyl

catheters (VII; Bolab) were also placed in the maternal femoral vein and the amniotic cavity. Fine stainless steel wires (Cooner Sales Co., Chatsworth, Calif.), were placed over the fetal sternum for recording of the electrocardiogram (ECG). The uterine incision was repaired and the control cable for the vascular clamp, as well as all catheters and electrodes, were exteriorized to the ewe's flank.

Sodium penicillin G (1,000,000 units) was infused into the fetus and the amniotic cavity at the time of surgery and daily for the next 3 days. Sodium penicillin G (800,000 units) and streptomycin (250 mg) were injected intramuscularly to the ewe at the same time intervals. The ewes were housed in individual cages, with free access to food and water, and were allowed at least 5 days to recover from surgery before any experiments commenced. The use of animals for these studies was approved by the University of Western Ontario Council on Animal Care in keeping with guidelines provided by the Canadian Council on Animal Care.

Experimental protocol. All experiments began at 10 AM and consisted of a 24-hour control period during which continuous recordings of FHR were made. The vascular clamp was then manipulated to reduce the fetal arterial oxygen saturation by approximately 40%. Fetal arterial blood samples were drawn initially at 5, 10, and 15 minutes to ensure a stable reduction in fetal arterial oxygen saturation. Fetal arterial blood samples were subsequently obtained at intervals of 2 to 4 hours for a further 24 hours for measurement of blood gas tensions, hemoglobin, and fetal arterial oxygen saturation.

Data analysis. The fetal ECG was recorded with an AC electroencephalogram preamplifier (model 7P511, Grass Instruments, Quincy, Mass.) with successive R-R intervals recognized by a microprocessor rate meter (JRAK Biosignals, Malvern, Australia). An error rejection algorithm excluded any intervals that were <80% or >120% of the previous valid interval. FHR was then sampled by a microprocessor (Hartronix, Toronto) every 200 msec and stored for subsequent off-line analysis. A baseline FHR was determined by the micropro-

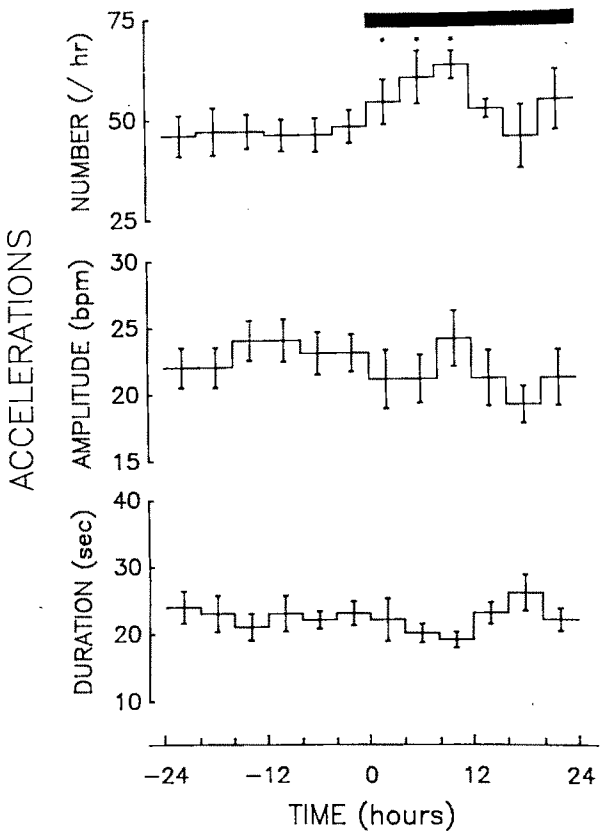

Fig. 2. Mean number per hour, amplitude, and duration of FHR accelerations in 4-hour epochs for the 24 hours before and 24 hours during hypoxemia indicated by the *solid bar*. $^*p < 0.05$.

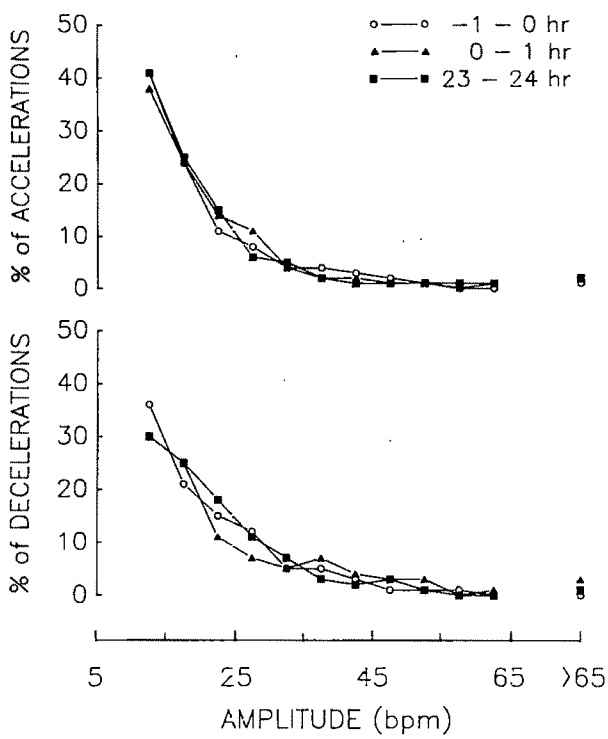

Fig. 3. Frequency distribution of the amplitude of accelerations and decelerations in intervals of 5 beats/min before and at 1 and 24 hours of hypoxemia.

cessor as the mean FHR over the previous 5 minutes, and accelerations and decelerations were identified as transient increases or decreases in the FHR of >10 beats/min lasting for ≥5 seconds. Fig. 1 demonstrates a typical example of the mean FHR of a sheep fetus at 130 days' gestation with the baseline superimposed.

Arterial oxygen tension, carbon dioxide tension, and pH were measured with an ABL glood gas analyzer (Radiometer, Copenhagen) at 37° C and then corrected for a fetal temperature of 39° C. Arterial oxygen saturation and hemoglobin were measured with an OSM2 Hemoximeter instrument (Radiometer). All results are presented as mean values ± SEM. Statistical significance was determined with either a one-way or two-way analysis of variance with repeated measures where appropriate.[8]

Results

Blood gas tensions and fetal arterial oxygen saturation. There was a significant decrease ($p < 0.001$) in both fetal P_{O_2} and fetal arterial oxygen saturation from control values of 22.3 ± 1.8 mm Hg and 54.6% ± 3.1%, respectively, which was maintained for the duration of the 24 hours (Table I). There was a small but significant decrease ($p < 0.05$) in fetal arterial pH from 7.34 ± 0.01 during the control period to 7.20 ± 0.05 at 2 hours of hypoxemia although pH subsequently returned to near-normal values This decrease in pH was largely due to the decrease ($p < 0.05$) in base excess from 0.3 ± 0.6 before the onset of hypoxemia to −6.7 ± 2.0 at 2 hours (Table I). There was a small, nonsignificant increase in fetal arterial P_{CO_2} from 49.4 ± 0.9 mm Hg during the control period to a maximum value of 55.2 ± 2.0 mm Hg at 1 hour of hypoxemia. There was no significant change in fetal hemoglobin concentrations from control values of 9.1 ± 0.5 gm/dl during the experimental period.

Mean FHR. There was an initial decrease in the mean FHR after manipulation of the vascular clamp, as reported previously.[9] This decrease was followed by a tachycardia with the maximum increase in mean FHR seen at 12 hours (Table I). There was no significant change in the fail time of FHR analyzed from 3.4% ± 0.9% during the 24-hour control period to 4.5% ± 1.9% during the 24 hours of hypoxemia.

Accelerations. There was no significant change in the mean number per hour, amplitude, or duration of accelerations during the 24 hours before the onset of hypoxemia (Fig. 2).

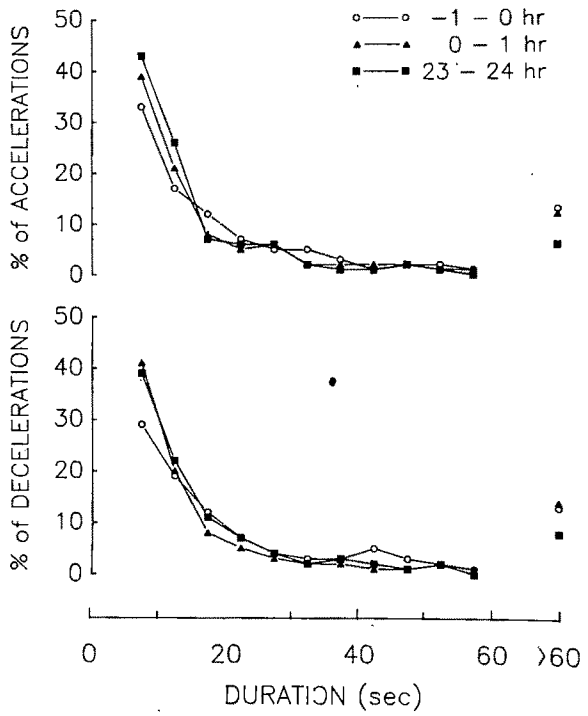

Fig. 4. Frequency distribution of the duration of accelerations and decelerations in 5-second intervals before and at 1 and 24 hours of hypoxemia.

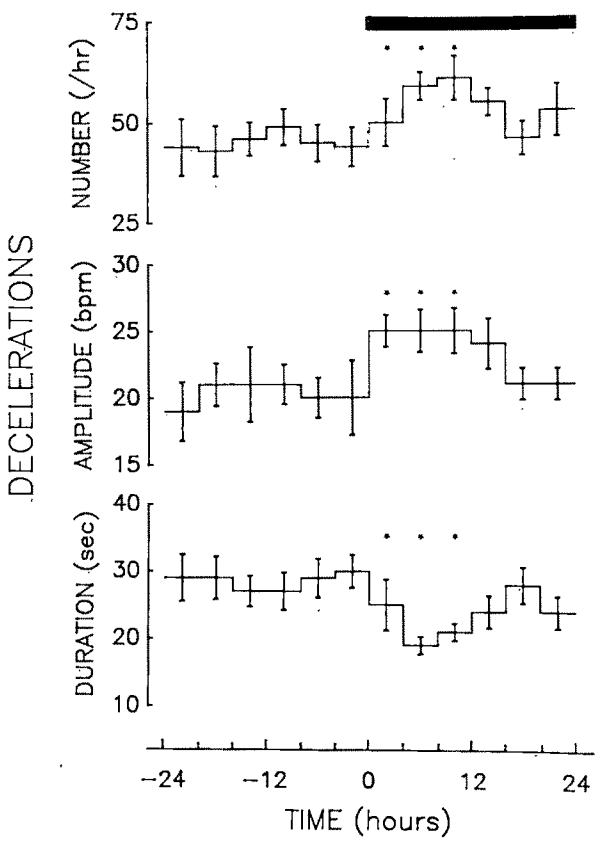

Fig. 5. Mean number per hour, amplitude, and duration of FHR decelerations in 4-hour epochs for the 24 hours before and 24 hours during hypoxemia, indicated by the *solid bar*. $*p < 0.05$.

There was a significant increase ($p < 0.01$) in the number of accelerations from 48 ± 4 per hour during the 4 hours immediately before the onset of the restriction in uterine blood flow to a maximum of 63 ± 4 per hour at 8 hours of hypoxemia. This was followed by a return to control values for the number of accelerations per hour by 12 hours of hypoxemia (Fig. 2). There was no significant change in the mean amplitude or duration of accelerations (Fig. 2).

There were no significant changes in the frequency distribution of the amplitude of accelerations at 1 hour or at 24 hours of hypoxemia when compared with the control period (Fig. 3).There was also no significant change in the frequency distribution of the duration of accelerations at 1 and 24 hours of hypoxemia (Fig. 4).

Decelerations. There was no significant change in the mean number per hour, amplitude, or duration of decelerations during the 24 hours before the onset of hypoxemia (Fig. 5).

There was a significant increase ($p < 0.01$) in the number of decelerations from 44 ± 5 per hour during the 4 hours before the onset of the restriction in uterine blood flow to a maximum of 61 ± 6 at 8 to 12 hours of hypoxemia (Fig. 5). The number of decelerations per hour then returned to control values.There was a significant increase ($p < 0.05$) in the mean amplitude of decelerations from 20 ± 1.2 beats/min during the control period to 25 ± 1.6 beats/min during the first 16 hours of hypoxemia followed by a return to control values (Fig. 5). There was also a significant decrease in the mean duration of decelerations from 29.9 ± 2.5 seconds during the control period to 19 ± 1.3 seconds at 4 to 8 hours of hypoxemia. This was followed by a return to control values (Fig. 5).

There was no significant change in the frequency distribution of amplitude (Fig. 3) or duration (Fig. 4) of decelerations at 1 and 24 hours of hypoxemia when compared with the control period.

Comment

In this study we have shown that prolonged hypoxemia in fetal sheep, which is secondary to the restriction of uterine blood flow, leads to an initial increase in the number of FHR accelerations and decelerations. This extends the observations of our previous study in which we found that 2 hours of hypoxemia of similar severity in fetal sheep leads to an increase in the number of decelerations.[7] These results are consistent with the findings of Dalton et al.[10] and Parer et al.,[11] that short-term hypoxemia induced by having the ewe inspire a

reduced oxygen gas mixture leads to an increase in both beat-to-beat variability and the 2-minute standard deviation of fetal heart periods. Huch et al.[12] also demonstrated that FHR variability in the human fetus during labor may be either increased or unchanged with hypoxemia as indicated with a transcutaneous Po_2 electrode.

In our study the increase in accelerations and decelerations was maintained for 12 to 16 hours, during which time the fetal arterial oxygen saturation remained significantly depressed at approximately 60% of control values. In fetal sheep FHR variability does not decrease with acutely induced maternal hypoxemia until severe metabolic acidemia has developed.[10] In our study acidemia, which was both metabolic and respiratory, occurred initially but pH returned to near-normal values by 12 hours. The effect of metabolic acidemia alone on FHR accelerations and decelerations is not known although it may contribute to the changes observed in this study.

It is of particular interest that the pattern of FHR accelerations and declerations returned to that of the normoexemic fetus by 16 hours, despite a persistent reduction in both fetal arterial Po_2 and fetal arterial oxygen saturation. This same time period of adaptation by the sheep fetus to prolonged hypoxemia that is secondary to the restriction of uterine blood flow occurs for behavioral activity.[13] The presence of FHR accelerations is closely linked to skeletal muscle activity in both the sheep and the human fetus.[3-6] Therefore the return to FHR patterns similar to that of the normoexemic fetus observed in this study may be a further indication of the behavioral adaptation to prolonged hypoxemia by the sheep fetus.

In these experiments, as in our previous studies, we observed an initial reflexively mediated bradycardia followed by a prolonged tachycardia. By 24 hours of hypoxemia, mean FHR returned to near-normal values although the redistribution of blood flow within the fetus, to the brain, heart, and adrenal glands, persists.[9] Since oxygen delivery to the brain is maintained by this increase in blood flow, despite a constant reduction in both fetal arterial oxygen saturation and Po_2, the alterations in FHR regulation observed under these experimental conditions do not appear to be mediated by either arterial oxygen tension or oxygen content alone. The increase in the number of FHR accelerations and decelerations and in mean FHR during the first 16 hours of hypoxemia may, however, be related to a prolonged increase in fetal plasma catecholamine concentrations, which has recently been observed under similar conditions of prolonged hypoxemia secondary to the restriction of uterine blood flow (Hooper S, Coulter C, and Harding R. Monash University, Melbourne, Australia, personal communication). Although short-term infusion of epinephrine to fetal sheep leads to an increase in FHR variability,[10] the effect of a prolonged increase in circulatory plasma catecholamine concentrations on FHR accelerations and decelerations in sheep is unknown.

Acutely induced hypoxemia in fetal rhesus monkeys also results in an increase in FHR variability, although the effects are greater on short-term than on long-term variability.[14] The appearance of late decelerations in FHR has been reported to occur before the loss of accelerations in spontaneous onset hypoxemia with progressive acidemia in rhesus monkeys.[15] There are no reports in the literature regarding the effects of more prolonged hypoxemia in the absence of acidemia on FHR variability in nonhuman primates.

It is of note that these findings of an initial increase in the number of accelerations and decelerations in fetal sheep with prolonged hypoxemia differ from that thought to occur in the human fetus. The prolonged absence of accelerations in the FHR (>80 minutes) is associated with a very high incidence of fetal hypoxemia and acidemia and with an increase in both perinatal morbidity and mortality.[16, 17] Smith et al.[18] have recently reported a decrease in the number of accelerations, as well as in the mean minute range, in preterm human fetuses delivered by cesarean section. These fetuses were subsequently found to have lower umbilical artery Po_2 values than fetuses with normal FHR characteristics. It is possible that if we had maintained the reduction in oxygen delivery to the fetus for a longer period of time we would eventually have observed a decrease in the number of FHR accelerations, as is seen in the human fetus. In addition, it is important to note that the sheep fetuses studied in this experimental protocol were all previously healthy and appropriately grown for gestational age. The effects of reduced uterine blood flow on FHR accelerations and decelerations in the growth-restricted sheep fetus are unknown, although they may more closely resemble those seen in the human fetus.

We thank Drs. B. S. Richardson, J. Patrick, and J. R. G. Challis for their interest in this work, Mrs. V. Ramsay for her excellent technical assistance, and Mrs. H. Cheung for statistical advice.

Prolonged hyperinsulinemia reduces plasma fatty acid levels in the major lipid groups in fetal sheep

Paul L. Ogburn, Jr., MD, Marshall Goldstein, MD, Jane Walker, BS, and Barbara S. Stonestreet, MD

Providence, Rhode Island

The offspring of women with poorly controlled diabetes have increased total body fat. Experimental fetal hyperinsulinemia has previously been associated with increased fat accumulation in rhesus monkey fetuses and increased lipid content and lipogenesis in rat fetuses. We hypothesized that prolonged fetal hyperinsulinemia would alter plasma total fatty acids and the individual fatty acids in each major lipid group. Fatty acids determined by gas-liquid chromatography were measured in the arterial blood of 12 chronically catheterized fetal sheep after 10 to 12 days of insulin ($n = 7$) or placebo ($n = 5$) infusion. Plasma concentrations of insulin were 412 ± 63 μU/ml and 9 ± 3 μU/ml (mean ± SE) in the insulin- and placebo-treated fetal sheep, respectively. Prolonged fetal hyperinsulinemia was associated with lower circulating total fatty acid levels in each lipid class except cholesterol esters. Although the precursor of arachidonic acid, 18:2 (linoleic acid), was not decreased in any lipid class, insulin infusion was associated with reduced arachidonic acid in each lipid class. We conclude that prolonged fetal hyperinsulinemia decreases circulating total fatty acid and the individual fatty acids in each of the major lipid classes, except for the cholesterol esters. We speculate that these reductions in circulating fatty acids represent an insulin-mediated increase in tissue deposition. (Am J Obstet Gynecol 1989;161:728-32.)

Key words: Insulin, fetus, fatty acids, arachidonic acid, infant of diabetic mother

In pregnancies complicated by diabetes mellitus, maternal hyperglycemia (and consequently fetal hyperinsulinemia) has been suggested to be the cause of perinatal morbidities in the offspring.[1] Large-for-gestational-age infants of mothers with diabetes have been reported to have increased fat accumulation.[2] Fetal hyperinsulinemia in the absence of hyperglycemia accelerates fetal growth in the rhesus monkey fetus[3] and enhances fatty acid synthesis in overgrown rat fetuses.[4] Because insulin increases fetal growth, including the deposition of fat, one might anticipate that fetal hyperinsulinemia would be associated with altered plasma fatty acids in each of the major lipid components. Therefore, in conjunction with other studies of fetal hyperinsulinemia,[5] we evaluated the effect of hyperinsulinemia on total fatty acid levels and individual fatty acids in each major lipid components by comparing plasma values in insulin- and placebo-treated fetal sheep to test the hypothesis that the plasma fatty acid patterns are selectively altered by insulin treatment.

Material and methods

The preparation of these animals and the experimental protocol have been previously reported in detail.[5] Surgery was performed on 12 pregnant mixed breed Eastern ewes with known breeding dates. Polyvinyl catheters were placed in the fetal descending aorta and inferior vena cava through pedal arteries and veins. The ewes were housed in the animal care facility postoperatively and for the duration of the experimental protocol and were allowed free access to food and water.

At 4 to 6 days after surgery, and at 123 to 126 days' gestation (term gestation is 150 days), the chronically catheterized fetal sheep were assigned to prolonged insulin- ($n = 7$) or placebo-infused ($n = 5$) groups. Insulin or placebo was then infused into a fetal vein continuously for 9 to 12 days. In the insulin-treated fetal sheep, 5 U/ml of purified porcine insulin (Iletin II, Eli Lilly and Co., Indianapolis, Ind.) was administered in a solution of 0.9% saline, 1.6% glycerol, 0.25% normal sheep serum, 1000 U/ml penicillin G, and 100 U/ml heparin at a rate of 3 ml/day of insulin. In the control group, a placebo infusion was administered at the same rate. After a mean of 11 days of prolonged infusion in each group, fetal arterial plasma samples were obtained to determine plasma insulin and circulating fatty acid levels in the major lipid groups.

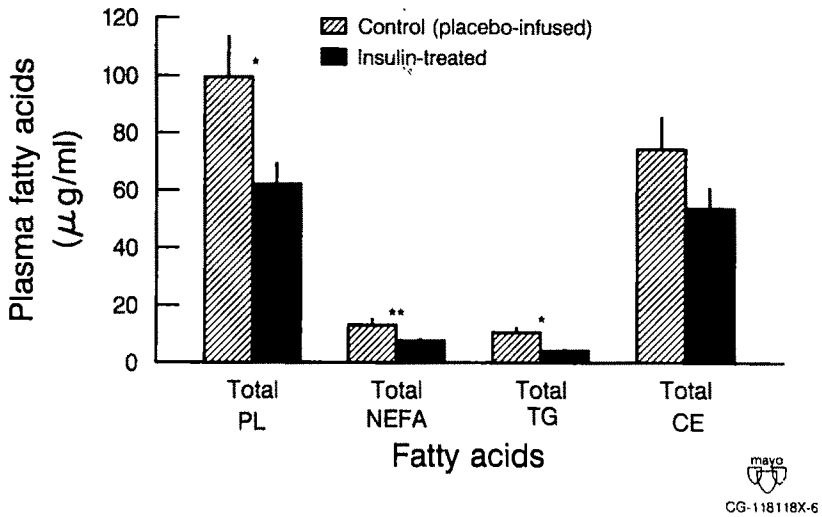

Fig. 1. Plasma concentrations of total fatty acids were significantly decreased in insulin-infused fetal sheep in phospholipids *(PL)*, nonesterified fatty acids *(NEFA)*, and triglycerides *(TG)*, but not in cholesterol esters *(CE)*. (Mean ± SE, $*p \leq 0.01$, $**p \leq 0.02$.)

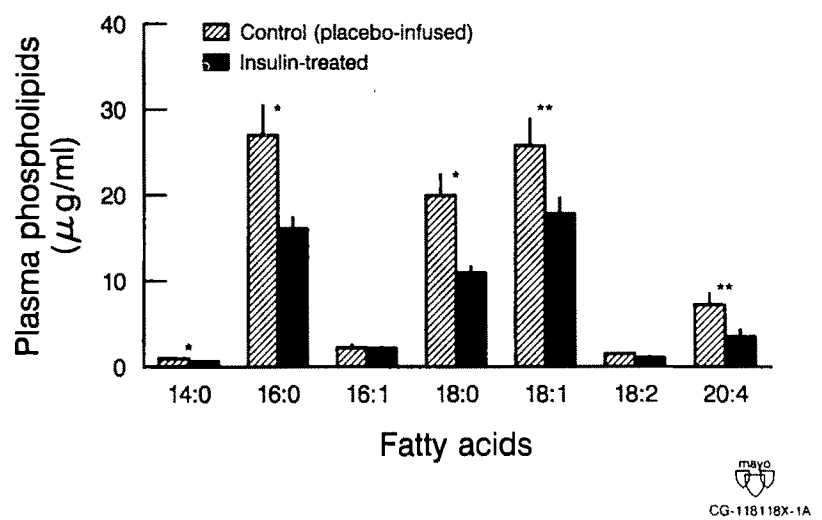

Fig. 2. Plasma concentrations of major fatty acids were decreased in phospholipids in insulin-infused fetal sheep. Major individual fatty acids measured included myristic (14:0), palmitic (16:0), palmitoleic (16:1), stearic (18:0), oleic (18:1), linoleic (18:2), and arachidonic (20:4). (Mean ± SE, $*p \leq 0.01$, $**p \leq 0.02$.)

Analytic methods. Plasma insulin concentrations were determined by a double antibody radioimmunoassay.[6] Fetal arterial samples obtained to assess fatty acids in the major lipid groups were immediately centrifuged and the plasma was frozen at −20° C until analysis. For each analysis, 1 ml of plasma was extracted with chloroform/methanol (1:1) with a modified Bligh and Dyer technique.[7] Substituted forms of heptadecanoic acid (17:0) were added as internal standards to quantitate the phospholipids, triglycerides, nonesterified fatty acids, and cholesterol esters. Details of extraction and production of the methyl esters have been previously published.[5] The fatty acid methyl esters were extracted with petroleum ether and stored under nitrogen at −4° C until quantitation with capillary column gas-liquid chromatography (United Technologies/Packard Model 439, Downers Grove, Ill.). Fused silica capillary columns were used with a liquid phase of 007F/FAP, 50 m × 0.25 mm (Quadrex, New Haven, Conn.). Fatty acids were quantitated on a computing integrator (Spectra Physics model 4200, San Jose, Calif.) by comparison with the heptadecanoic acid internal standards. Retention times were determined by known standards. Other fatty acids were seen in much

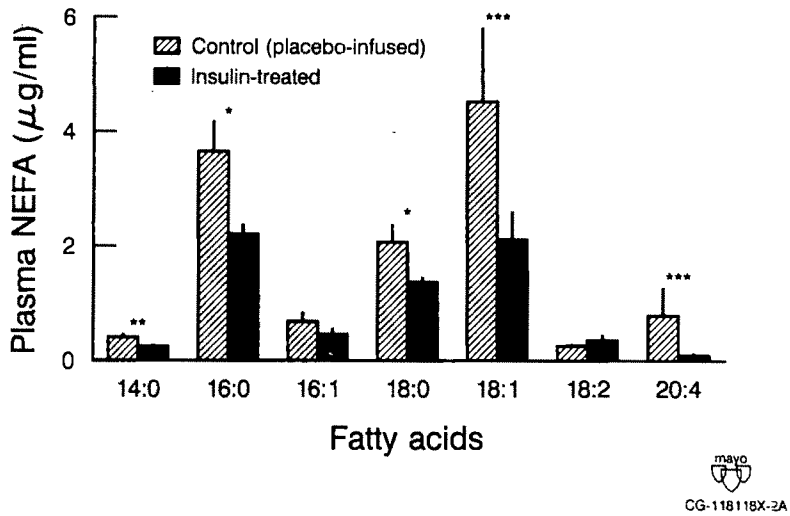

Fig. 3. Plasma concentrations of major fatty acids were decreased in nonesterified fatty acids in insulin-infused fetal sheep. Major individual fatty acids measured included myristic (14:0), palmitic (16:0), palmitoleic (16:1), stearic (18:0), oleic (18:1), linoleic (18:2), and arachidonic (20:4). (Mean ± SE, $*p \leq 0.01$, $**p \leq 0.02$, $***p \leq 0.05$).

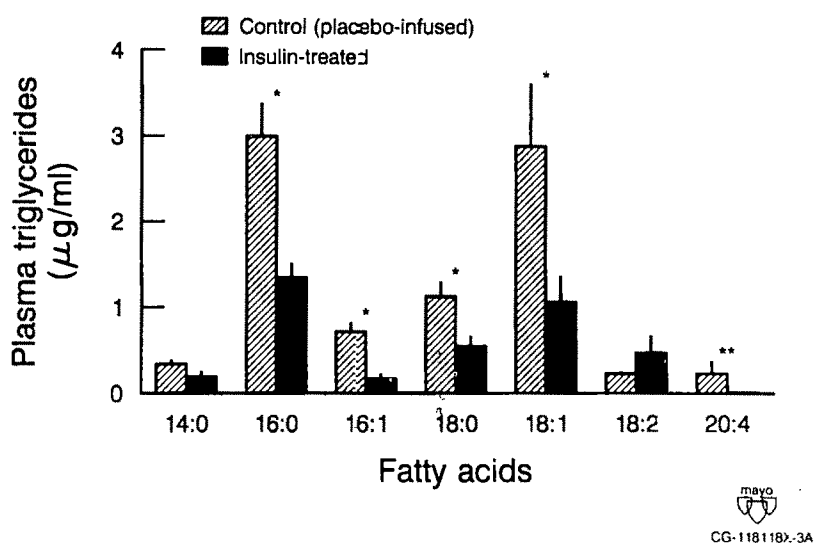

Fig. 4. Plasma concentrations of major fatty acids were decreased in triglycerides in insulin-infused fetal sheep. Major individual fatty acids measured included myristic (14:0), palmitic (16:0), palmitoleic (16:1), stearic (18:0), oleic (18:1), (18:2), and arachidonic (20:4). (Mean ± SE, $*p \leq 0.01$, $**p \leq 0.02$.)

smaller quantities and are not part of the calculations.

Statistical analysis. The two-tailed unpaired Student *t* test was used to evaluate differences between means of the insulin- and placebo-treated fetal sheep for all fatty acid values reported. Results were reported as mean ± SEM; $p < 0.05$ was considered statistically significant.

Results

After 11 days of infusion, the insulin concentration was 412 ± 63 μU/ml and 9 ± 3 μU/ml (mean ± SE) in the insulin- and placebo-treated fetal sheep, respectively. The total plasma fatty acids of phospholipids, nonesterified fatty acids, and triglycerides each were significantly decreased in the insulin-infused fetal sheep (Fig. 1). Circulating fatty acid quantities and patterns for phospholipids, nonesterified fatty acids, and triglycerides are shown in Figs. 2, 3, and 4. Most of the major individual fatty acids, including arachidonic acid, were decreased in the insulin-treated sheep. Linoleic acid did not follow this pattern in any lipid groups. Cholesterol esters, unlike the other lipid groups, did

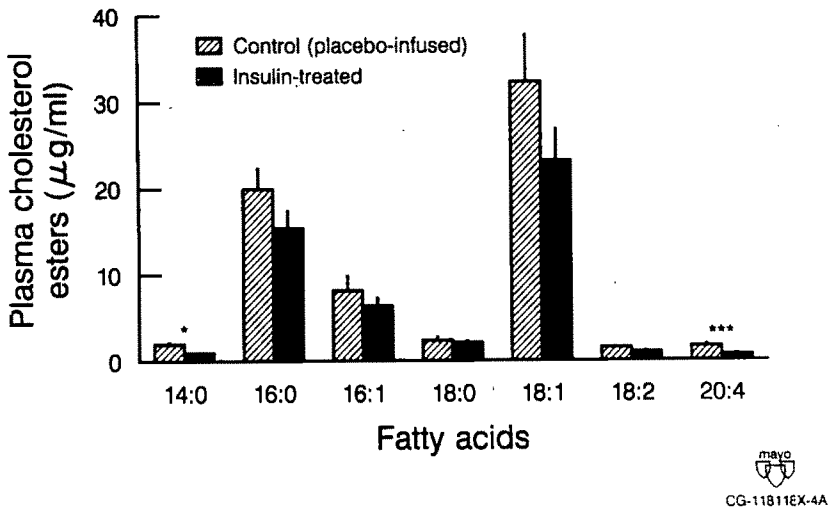

Fig. 5. Plasma concentrations were not consistently altered in cholesterol esters in insulin-infused fetal sheep. Major individual fatty acids measured included myristic (14:0), palmitic (16:0), palmitoleic (16:1), stearic (18:0), oleic (18:1), linoleic (18:2), and arachidonic (20:4). (Mean ± SE, $*p \leq 0.01$,$***p \leq 0.05$.)

not show significant decreases in the circulating fatty acids in the insulin-treated fetal sheep (Fig. 5).

Comment

Insulin treatment for 11 days selectively reduced circulating phospholipid, triglyceride, and nonesterified fatty acids in the fetus. Because insulin promotes the movement of glucose and nonesterified fatty acids into cells including adipocytes for triglyceride production,[8] these reduced plasma levels may reflect increased tissue deposition for fat accumulation in the hyperinsulinemic fetus.[3,4] This concept is supported by insulin enhanced fatty acid synthesis in hyperinsulinemic rat fetuses.[4] Moreover, sustained hyperinsulinemia may diminish lipolysis, contributing to the lower circulating nonesterified fatty acid levels for production of liver phospholipids and triglycerides.[9] Therefore we speculate that the reduced total fatty acid plasma levels in our hyperinsulinemic fetal sheep may reflect increased fat synthesis and reduced lipolysis for the production of lipid-rich tissues in the fetus.

Linoleic acid is the precursor of arachidonic acid and, therefore, an essential fatty acid. Unlike arachidonic acid, however, it did not show significant decrease in response to insulin infusion. This may be, in part, because of relatively low levels of linoleic acid in the circulation of fetal sheep. It is possible that most of the linoleic acid available to the ovine fetus is converted to arachidonic acid before significant accumulation occurs in the fetal compartment. Another possibility might be that elongation of linoleic acid to arachidonic acid is reduced by insulin treatment of the fetus. On the other hand, preferential uptake of linoleic acid, and thus its removal from circulation by fetal tissues of diabetic rats, has been reported.[10]

Alterations in cholesterol esters were not as great as those of the other lipid components, which suggests that production in the fetus is less insulin-dependent. There is evidence that cholesterol esters are transported to the fetus from maternal circulation, and very little may be made directly by the fetus.[11]

It is well established that increased insulin availability decreases nonesterified fatty acids and triglycerides in the plasma of adults, fetuses, and neonates in some animal models.[8-11] There is also evidence that, at least in human beings and sheep, fetal plasma lipid levels are much lower than those of the maternal compartment.[9-13]

Prior work has suggested that hyperinsulinemia in the fetus leads to increased deposition of fatty acids into fat and other tissue stores.[1,2,4,8-11] The present study suggests that the immediate source of these fatty acids is in part the circulating lipids (triglycerides, nonesterified fatty acids, and phospholipids) whose levels are decreased by the action of insulin.

We acknowledge Dennis Berard for his excellent technical assistance and the continued support of William Oh, MD.

Pharmacokinetics of azidothymidine during late pregnancy in Long-Evans rats

B. B. Little, MA, PhD, R. E. Bawdon, PhD, J. T. Christmas, MD, S. Sobhi, BS, and L. C. Gilstrap III, MD

Dallas, Texas

Azidothymidine (Zidovudine) is used to treat symptomatic human immunodeficiency virus infection. It has the ability to reverse seropositivity as well as decrease serum viral titers, and perhaps decrease potential for transmission of the virus. An animal model (pregnant Long-Evans rats) was used to investigate the potential for placental transmission of azidothymidine. The drug crosses the placenta to reach concentrations in the placenta and fetus that are comparable to 75% and 58%, respectively, of those in the maternal serum by 2 hours after administration. By 4 to 6 hours after administration azidothymidine concentrations in the placenta and fetal liver significantly exceed maternal concentrations. (AM J OBSTET GYNECOL 1989;161:732-4.)

Key words: Azidothymidine, pharmacokinetics, pregnancy, human immunodeficiency virus, placental transfer

Azidothymidine (AZT) (Zidovudine, Burroughs Wellcome, Research Triangle Park, N.C.) is used in the treatment of symptomatic human immunodeficiency virus (HIV) infection. AZT has recently been reported to transiently reverse HIV seropositivity and reduce serum viral titers.[1] Furthermore, the drug may reduce the infectious state of an HIV-positive person.[2] The risk of perinatal HIV transmission from mother to fetus is unknown but appears high with 25% to 60% of infants born to HIV-positive mothers becoming seropositive in early infancy.[3-5]

It is conceivable that the drug may be used to treat women of reproductive age, and such women may become pregnant. AZT's ability to cross the placenta is of fundamental importance to evaluate this situation. There are no published data available with regard to placental transfer of this antiviral agent.

The purpose of this study was to evaluate the placental transfer of AZT in a rat animal model.

Material and methods

Long-Evans rats were chosen as the animal model for analysis of placental transfer of AZT because (1) this species has been used in similar studies, (2) the size is convenient for handling and dissection, and (3) the rats have a known heritage for many generations and

are genetically homogeneous. A total of 16 timed pregnant Long-Evans rats were obtained from a commerical vendor and maintained on regular rat chow and water as desired in our Animal Resources Center until the eighteenth day of pregnancy. This study was approved by the Institutional Review Board for Animal Research. On the eighteenth day of pregnancy rats were orally given 30 mg/kg of AZT, and were killed by decapitation at the following time intervals: 0.5, 0.75, 1.0, 1.5, 2.0, 4.0, and 6.0 hours. Two rats were assigned to each treatment group, and two rats were not pregnant. The reason two rats per time period were used is because (1) this is the minimum number of animals possible to compute SD, error, and Student *t* test statistics, and (2) a paired Student *t* test (degrees of freedom = 2) can detect differences in concentration of the magnitude of a half-life as statistically significant with this sample size ($\alpha = 0.05$, $\beta = 0.90$). Maternal blood was collected at the time of decapitation, and fetuses and placentas were immediately removed by cesarean section. These samples were frozen at −4° C after collection and thawed to room temperature at the time of analysis.

Maternal serum, placental tissue extracts, and fetal liver homogenates were analyzed by high-performance liquid chromatography for AZT concentrations. All assays were performed with a guard column between the injection pump and the high-performance liquid chromatography column. Samples for assay were prepared for analysis by direct injection of the centrifuged tissue homogenate. Serum specimens were assayed by precipitation with an equal volume of acetonitrile. The specimens were vortexed for 15 seconds and centrifuged at 3000 *g* for 15 minutes. Assays were accomplished with a Waters 481 detector (wavelength = 254 mm), a C_{18} Micro-band-a-pak column and a Beckman 110 pump. The mobile phase was 16% acetonitrile and 84% 0.1 mol/L phosphate buffer with a pH of 2.5. The flow rate was 2.0 ml/min.[6] Between-batch and within-batch reproducibility studies were performed, and differences were <5%, well within acceptable limits.

Results

AZT concentrations in maternal serum dropped quickly, decreasing by half in the first hour (Table I), which correlates with the reported half-life of the drug in human patients (60 minutes).[7] By 30 minutes after administration, placental tissues attained concentrations of about one seventh, and fetal liver contained

concentrations of about one eighteenth of those in maternal serum, significantly different by paired Student *t* test ($p < 0.01$) (Table II). At 2 hours after dosing, concentrations in all three tissues were similar. Maternal serum and placental tissue achieved concentrations slightly higher than the fetus (Table I).

There was rapid clearance of AZT from maternal serum, with nearly undetectable levels by 4 to 6 hours after administration. However, at 4 to 6 hours after administration, both fetal and placental AZT levels remained four to five times higher than maternal levels ($p < 0.05$; Fig. 1), near the lower range for the serum of human adults who receive therapeutic doses.

Comment

Results of the present study indicate that, in the rat, AZT rapidly crosses the placenta. Whereas the drug rapidly cleared from the maternal compartment, it appears to be concentrated in the fetoplacental compartment. There are at least two mechanisms by which the findings of this study could be explained. Approximately 40% of AZT becomes glucuronoside in the first pass through the liver in adults. This AZT glucuronoside is inactive as an antiviral agent and ultimately is excreted by the kidneys.[8] Decreased hepatic metabolism in the immature fetal liver may, therefore, be responsible for persistence of significant levels in the fetal compartment.

A second possible mechanism for the findings of fetal and placental concentration of the agent involves the method of placental transfer. Preliminary studies at our institution with explanted human placental cotyledons suggested that AZT is actively transported across the human placenta into the fetal compartment.[6] Active transport could easily explain the results of this study with persistent levels in both fetal liver and placental tissue. Safety of AZT during pregnancy is, therefore, an issue because if maternal exposures occur, embryofetal exposure also seems probable. the teratogenic potential of the drug appears low in rats born to mothers who were given several times the usual human dose during early or late embryogenesis (unpublished observations). However, rodent animal models are typically poor predictors of human teratogenic potential.[9]

Further studies of AZT in human beings or nonhuman primates are needed confirm a low teratogenic potential, and to verify active placental transport of this agent. Caution must be used when extrapolating findings of animal studies of both placental transfer and teratogenicity to the condition in human beings because the composition of the rat placenta and development of the rat conceptus are different from the human placenta and conceptus. Although both are hemochorial placentas, in the rat there is a layer of cellular trophoblast interposed between the chorionic villus and maternal blood. This may cause species differences in the drug's kinetics across the placenta. However, despite differences in placental morphology, the results of this study concur with our findings in explanted human placental cotyledons,[6] and suggest that substantial amounts of AZT cross the placenta and reach the developing conceptus.

Ultrastructural aspects of preeclampsia

I. Placental bed and uterine boundary vessels

Douglas R. Shanklin, MD, and Baha M. Sibai, MD

Memphis, Tennessee

Biopsy specimens were obtained under direct vision at the time of cesarean section from 42 patients (33 preeclamptic and nine normotensive patients) and from three hysterectomies (all in normotensive patients). Mean gestational age was 32.8 ± 0.9 weeks (range, 26 to 40 weeks) in women with preeclampsia and 36.1 ± 1.1 weeks in normotensive women (range, 32 to 41 weeks). Tissues were obtained from the central placental bed and from nonplacental sites. Specimens were examined histologically and by electron microscopy. Ultrastructural changes in small vessels, primarily venules, were compared with preeclamptic blood pressure. Extensive ultrastructural endothelial injury was found consistently in both site and nonsite areas in all of the specimens from women with preeclampsia but not in normotensive women ($p < 0.0001$). There was no apparent correlation between the type or degree of endothelial damage and maternal hypertension. The same types and relative severity of specific vascular injury were present in both placental and nonplacental sites. Endothelial and derivative vascular injury occurs more or less uniformly in the uterus in preeclampsia, especially along the boundary zone between maternal and fetal tissues. (Am J Obstet Gynecol 1989;161:735-41.)

Key words: Placental site biopsy. preeclampsia, vascular injury, ultrastructural changes, uterine boundary zone

The continuing search for both the cause and pathogenesis of preeclamptic toxemia (gestosis humanis) over the past 20 years has turned to the integrity of uterine vessels and changes in coagulation, which may relate to endothelial injury as shown by histologic and electron microscopic methods.[1-18] Histologic,[1-3, 9, 10, 13] transmission ultrastructural[5-7, 12, 13, 14, 18, 19] and scanning electron microscopic[17] studies have considered uterine arteries at several levels of the arborization, as shown especially clearly by Sheppard and Bonnar.[18, 19] Interest has been directed primarily at spiral arteries* and more general features of the placental bed.[1, 3, 5-7, 12-14, 17-19] These largely European studies have identified a number of lesions: acute atherosis,[1, 7, 10, 13] hyperplastic arteriosclerosis,[13] and alterations[1, 9, 13, 18, 19] in the expected physiologic restructuring of the spiral arteries during pregnancy.[3, 5, 6, 13, 14, 17-19] The cited articles account for at least 426 placental bed biopsies and samples of placental site tissue from uteri studied after cesarean section hysterectomy or pregnancy termination by earlier hysterectomy. Two large series were identified only as "over 100"[13] and "several hundred"[3] biopsies, comprising a possible total of perhaps 750 individual cases studied to date. This material was derived from clinical backgrounds of normal pregnancy,† preeclampsia or other hypertensive states,[2, 7, 9, 10, 13, 18, 19] and intrauterine growth retardation.[1, 10, 18, 19] Some studies included multiple categories of clinical condition of either mother or fetus.[1, 9, 10, 18, 19] Several studies also examined placentas,[2, 7, 10, 13, 18, 19] including two in which the placenta remained in situ after hysterectomy.[2, 13] The basic techniques for obtaining placental bed biopsies and an overview of the information obtained up to 1986 were summarized in a critical review by Robertson et al.[14] The observation that the placental bed is a heterogeneous tissue field, making sampling difficult, has been emphasized in a number of reports.[3, 13, 14] Less often, but no less emphatically, several comparative studies have indicated that no distinction can be made between normotensive and hypertensive cases by histologic or ultrastructural examination of spiral arteries,[18, 19] despite the finding by Brosens et al.[1] that acute atherosis was found principally in hypertension combined with fetal growth retardation and not in normotensive pregnancies, a finding later disputed presumptively by study of 39 placentas but not placental beds.[10]

In light of these studies and the ongoing need to elucidate primary vascular events in early preeclampsia, we began in mid-1987 to collect central placental bed biopsy material at time of cesarean section delivery with

Similar change in smaller venules or somewhat greater change in vessels of this size would show reduction in lumen. (Original electron microscopic magnification ×1600.)

simultaneous biopsy of nonplacental site uterine boundary tissue, with emphasis on smaller blood vessels. Histologic and transmission electron microscopic studies to date are the subject of this report. Extensive ultrastructural endothelial injury was found consistently in both placental site and uterine nonplacental site boundary myometrium in all of the specimens from the preeclamptic patients but not in specimens from normotensive women ($p < 0.0001$).

Material and methods

Informed consent for placental bed and uterine boundary biopsies was obtained from various patients in the prenatal clinics of the E. H. Crump Hospital who were scheduled for cesarean section for obstetric or perinatal indications. A total of 42 patients, 33 with preeclampsia (systolic blood presure >140 mm Hg, or diastolic blood pressure >90 torr or both, with proteinuria >300 mg/24 hours), and nine normotensive women had biopsies. Three cesarean section hysterectomies from normotensive patients were also studied; thus a total of 45 patients (12 normotensive and 33 hypertensive) was studied. At the time of cesarean section, biopsy specimens approximately 0.8 × 0.6 × 1.0 cm in size were excised by sharp dissection and were immediately placed in the appropriate fixative. Placental site samples were taken from the center of the attachment site just after placental removal, and comparable nonsite samples were taken from the opposite uterine wall. On receipt in the pathology laboratory, appropriate accession numbers were assigned and the samples were trimmed into pieces for paraffin or plastic embedding according to ordinary techniques, beginning with 10% neutral buffered aqueous formalin for histology and net 1.0% glutaraldehyde buffered in Sörenson's solution for ultrastructural study.

Paraffin sections were cut at 5 μm and were stained by hematoxylin and eosin for light microscopy. Histologic preparations were available for all 45 patients.

Plastic sections for electron microscopy were pre-

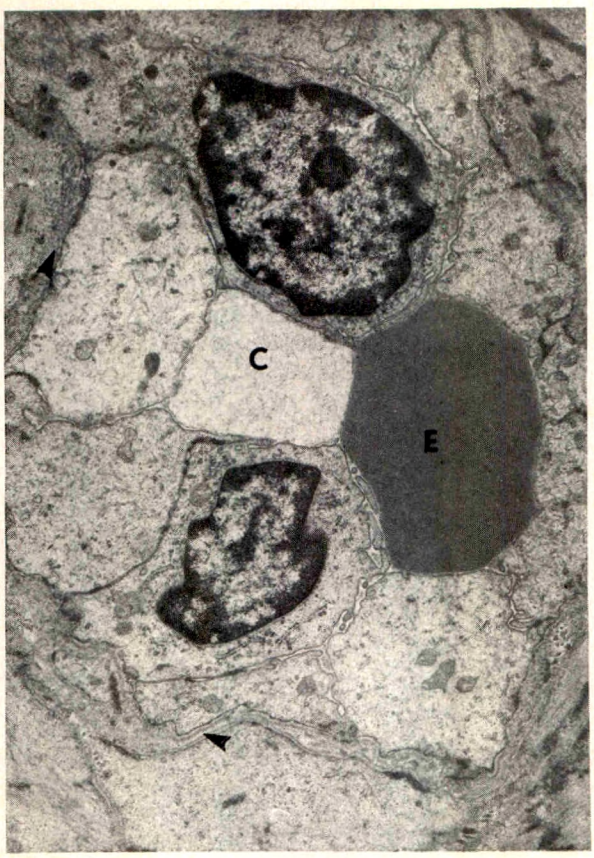

Fig. 3. Marked reduction of lumen of large venule, placental bed region of uterine boundary zone, preeclampsia. pared in the usual manner with lead acetate staining. Electron micrographs were taken at ×1600 to ×2500 original magnification in a Zeiss EM-10C and were printed at an average further enlargement of ×2.7. Electron micrographs were available for 27 of 33 preeclamptic women and for 9 of 12 normotensive women.

Results

Vascular and ultrastructural changes were compared between the two groups and with preeclamptic maternal blood pressure.

Clinical aspects. The average gestational age in preeclamptic pregnancies was 32.8 ± 0.9 weeks (range, 26 to 40 weeks) and 36.1 ± 1.1 weeks in normotensive pregnancies (range, 32 to 41 weeks; the difference was not significant, $t = 0.50$, $p > 0.5$). Maximum recorded blood pressures fulfilled criteria used in the primary diagnosis of preeclampsia (systolic blood pressure >140 mm Hg, diastolic blood pressure >90 torr, or both, with proteinuria >300 mg/24 hr). The variability of blood pressure in each patient was noted, but since no correlation with average or maximum values and tissue findings could be demonstrated, further correlation with the variability was not undertaken. There were no maternal deaths in this series. Perinatal mortality was low; there were no stillbirths and only one neonatal death in the hypertensive group, which yielded a group rate of 3.0% and 2.2% overall. None of these patients had eclamptic seizures.

The differences in blood pressures were strongly significant (systolic: $t = 10.5$, $p < 0.001$; diastolic: $t = 10.8$, $p < 0.001$). The more than 3-week difference in mean gestational age suggested some significance by Student's t test ($t = 2.32$, $0.05 > p > 0.02$). The F value for variation of population, however, was 5.38 (not significant), which devalued the t test result. We anticipate that enlargement of the normotensive portion of the series will further reduce this limited difference without impairing the distinction with regard to vascular injury.

Pathologic aspects. Histological findings were helpful in assessing the ultrastructural changes and will be described first.

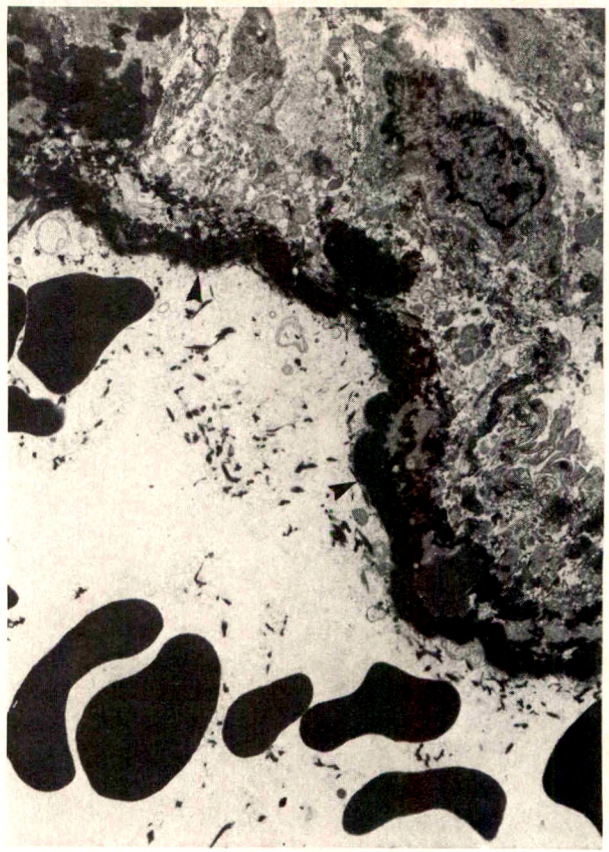

Fig. 6. Compacted heavy fibrin deposition *(arrows)* and loose luminal fibrin replacing extensively eroded endothelium, nonplacental site region, uterine boundary zone, preeclampsia. (Original electron microscopic magnification ×2500.)

Histologic changes. Histologic changes that were readily observed included some apparent medial hypertrophy of smaller arteries and arterioles, primarily but not exclusively in the placental site, dilated veins and venules with and without thrombosis, occasional placental site trophoblastic giant cells, focal hemorrhage, some interstitial edema, and uterine smooth muscle reflecting the expected gestational hypertrophy. The adaptive changes in spiral arteries were seen in most specimens, but no distinction with regard to degree or character of the change was observed between preeclamptic and normal subjects. Decidua and regressed or atrophic endometrial glands were observed less often. Occasional lymphocytes were found in the junctional tissues and occasional circulating blood elements, such as polymorphonuclear leukocytes, macrophages, and platelets were found in addition to many erythrocytes. Whereas overt thrombosis was uncommon, small foci of fibrin deposit were found more often, especially in relation to tears and erosions of the endothelium, and in overt tears into the perivascular space and myometrium. None of the changes were present such that unequivocal, consistent identification of placental site as opposed to nonplacental site sampling was possible. Placental site trophoblast, when present, would identify the site, but only one third of these biopsies contained trophoblast. The possibility that trophoblastic site giant cells may be found beyond the placental bed was enhanced by one case in which both biopsies contained them.

More importantly, an overall view of the boundary between the uterus and the placental sac is possible from a composite of these observations. Vascular injury and tears into uterine soft tissues, with hemorrhage, are commonplace; essentially these processes occur both in the placental site and elsewhere throughout the boundary zone either equally randomly or with comparable frequency. In fact, such observations make it possible to define the boundary zone as the combination of the atrophic or regressive endometrium, which is displaced and compressed by the pregnancy sac, plus the interdigitating connective tissues of the inner myometrium including blood vessels.

The ultimate maternal vascularization of the placental site is therefore a modification of this region, with

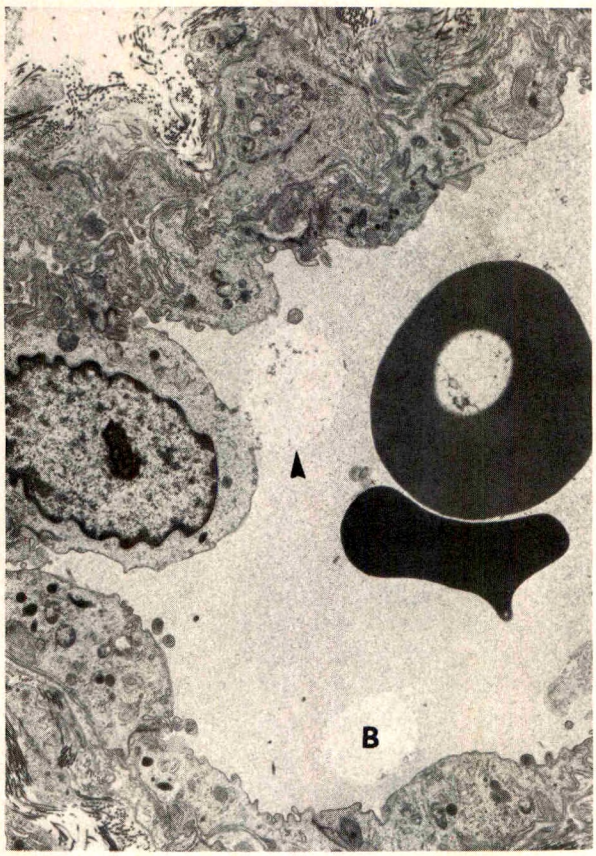

Fig. 7. Rupturing bleb *(arrow)* of endothelium, large venule, nonplacental site region of uterine boundary zone, preeclampsia. This is one possible precursor to overt paraluminal erosion of endothelium. Note a similar structure *(B)* near lower edge of photograph, protruding from a different level in the block. (Original electron microscopic magnification ×3150.)

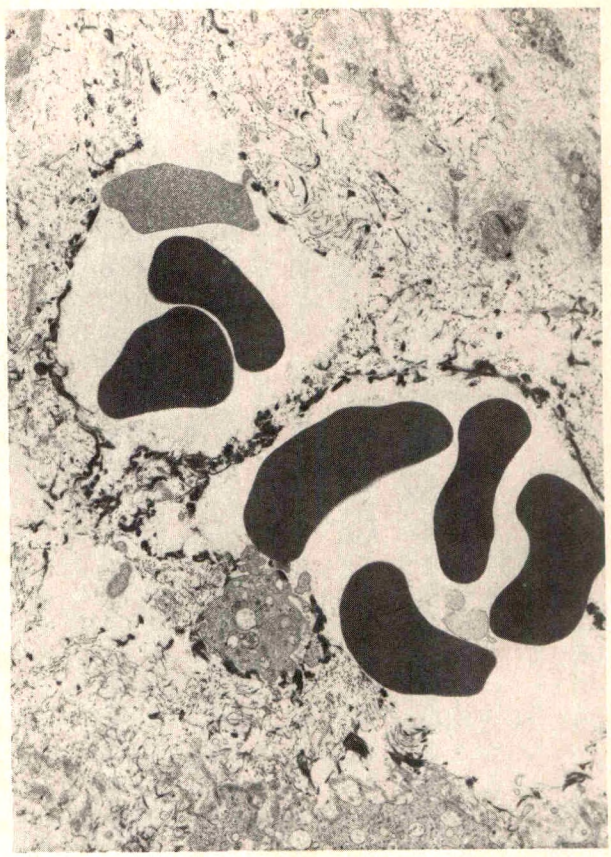

Fig. 8. Microhemorrhage into connective tissue of nonplacental site region of uterine boundary zone, preeclampsia. Note fibrin deposition onto surfaces of the dissection planes of the hemorrhage and the absence of venular media or basement membrane. (Original electron microscopic magnification ×2500.)

the added change of hypertrophy and dilation in the spiral arteries with additional changes in the deeper arterial arcades of the myometrium. Since the pathologic changes seemed to us to be more or less uniform throughout the boundary zone, the larger vessels beneath the placental site itself would appear to be less significant. Our subsequent studies of the ultrastructural details of these regions have confirmed the unitary and integral nature of the boundary zone.

Ultrastructural changes. There was no apparent correlation between the type or degree of endothelial damage and the level of maternal hypertension. Endothelial injury was pervasive in the preeclamptic women, but the same types and relative severity of specific changes were present in samples from both placental and nonplacental boundary sites. We concentrated on smaller vessels, particularly the venules, as the most likely site for injury (Figs. 1 and 2). The restricted size of electron microscopic samples signified that all kinds and degrees of change were not present in all cases. Nevertheless, a coherent spectrum of change was obvious. The endothelium was both swollen (Fig. 3) and eroded (Fig. 4). Even mild swelling was associated with enlargement of endothelial nuclei (Fig. 2); the result was apparent reduction of lumen (which was sometimes very extreme), with marked cytoplasmic swelling of endothelium and a reduced number of nuclei per cross-sectional field (Fig. 3). Luminal fibrin polymerization (Fig. 5) was observed in the case of both swollen and eroded endothelium, but was more obvious and more common with erosion (Fig. 6). In some cases erosion was incomplete with a light deposit of fibrin, but in others complete erosion was related to a heavy deposit (Fig. 6). Endothelial cytoplasmic tears short of erosion of the whole thickness were found, and as the sample became larger, at least one source for these focal tears became apparent: the endothelium occasionally showed vacuoles that enlarged into blebs bulging from the surface (Fig. 7). These blebs would then rupture, exposing the endothelial cytosol to the vascular lumen. Subendothelial edema was seen less often. Platelets

were found but not as a regular feature of these early lesions. Instead, linear or circumferential fibrin deposit seemed to be the principal means by which the earliest repair of the injury was attempted. Hemorrhages into the deeper boundary tissues, although not common, were almost always associated with fibrin deposit at that level (Fig. 8). The vacuoles have been identified as endothelial mitochondria, which initially show swelling with loss of cristae. A general expansion of cytoplasm, probably from electrolyte shifts, was a conspicuous feature. Platelet adhesion was observed, but was not a consistent feature. Altered permeability was seen occasionally with subendothelial plasma and fluid accumulation. Atherotic changes were not seen by electron microscopy; in two cases mucinous degeneration of larger vessels was seen on light microscopy.

Comment

As has been noted, prior studies have concentrated heavily on spiral arteries* in the placental bed.[1, 3, 5-7, 12, 13, 14, 17-20] Critical comparative studies have shown no effective distinction in spiral arteries in the placental bed between hypertensive and normotensive pregnancies,[18, 19] findings not explained by procedural and technical difficulties in obtaining biopsies.[14]

On a priori grounds, we considered that the effects of changes in coagulation factors seen in preeclamptic toxemia[4, 15, 16] and other aspects of the vascular lesion might be more easily identified in smaller vessels of the placental-maternal tissue boundary. The spiral arteries are subject to such profound physiologic adaptation,[3] and pathologic changes especially in late pregnancy,[13] that subtle lesions might not be easily distinguished. Moreover, recent challenges[10, 18, 19] to the putative specificity of acute atherosis and other changes in hypertensive pregnancies[7, 13] have led researchers to consider pathogenetic effects at differing zones or segments of the arterial tree.[1, 9, 12] In fact, the scope of sampling may need to be extended in three dimensions, since significant differences in abnormal uterine waveform velocity have now been described between the fundal and the low arcuate segment vascular fields.[11] Our observations extend this work with emphasis on the proximal venous side of the uterine boundary circulation. Understanding of the phenomenon of altered coagulation has also changed, with more precise and sensitive methods now available.[16] Some changes are present very early in pregnancy, such as decreased fibrinolytic activity (present by 12 weeks), and decreased fibrinolytic capacity (seen by 20 weeks).[4] Saleh et al.[16] examined clotting factors by a variety of techniques. They found levels of serum fibronectin to be increased and α_2-antiplasmin to be decreased in preeclampsia. Both levels returned toward normal post partum, with a greater relative change in patients with severe preeclampsia.[16]

It is tempting to consider that the increased fibronectin, a substance known to be produced by both liver and endothelium,[16] originates in the injured smaller vessels we have examined. Obviously, further study is necessary to establish the relationship of these observations. In particular, correlation with early changes in the coagulation mechanism must await the availability of appropriate uterine tissue from early second trimester, if not before. Earlier tissue samples might also provide information on the vascular adaptations that result, near term, in a lack of significant differences in vascular resistance and other circulatory parameters between preeclamptic pregnancy and the nonpregnant state, whereas normal pregnancy differs from both.[20] Meanwhile we are attempting to describe the mature vascular lesions in the third trimester. The existence of a circulating factor toxic to endothelium has been suggested by recent evidence.[15] It is unclear whether this is a primary agent or a factor involved in further pathogenesis promoting extension of the lesions.

The ultrastructural changes are those of endothelial injury, probably to cytoplasmic organelles and very possibly to mitochondria. Both diffuse and organelle swelling occur, and either leads to erosion of endothelium. Our observations suggest that this erosion begins with loss of the cortical cytoplasm rather than slough of the entire endothelial cell. Fibrin is deposited during the erosive process just as would occur in most forms of endothelial injury. Occasionally fluid appears to collect behind the endothelium. This can occur either by transudation or as dissection from another point along the vessel. Of interest are the recent studies of Glawanakowa and Popowa.[8] They examined peripheral blood for circulating desquamated endothelial cells and found a progressive rise during pregnancy, with a further increase in patients with edema-proteinuria-hypertension gestosis (preeclampsia). Once erosion has begun, whole-cell desquamation can proceed from that focus. Our later-stage lesions (Figs. 7 and 8) can represent either whole-cell desquamation or multistage erosion. Confirmation of the results of Glawanakowa and Popowa will contribute to a better understanding of the vascular effects of pregnancy as modified by preeclampsia. A major source for circulating endothelial cells might be the venules we have examined, since they are numerous. Our experience has shown that small vessels, particularly venules, are injured in preeclampsia irrespective of their location in the boundary zone. It remains to be determined whether comparable vascular injury occurs elsewhere in the uterus or in

*References 1, 3, 5-7, 9, 12-14, 17-19.

other body sites. Changes in endothelial organelles such as mitochondria suggest a metabolic link that merits further exploration.

We thank Deborah Hollis for preparation of tissues for electron microscopy and Frank Moretta for the electron micrographs.

Birth weight prediction from remote ultrasonographic examination

Joseph A. Spinnato, MD, Robert D. Allen, and Hiram W. Mendenhall, MD
Mobile, Alabama

Multiple linear regression by the least squares method was used to remodel five existing static equations to permit birth weight estimates from remote ultrasonographic parameters. By incorporating lapse time (examination-to-delivery interval), the new equations can be used to estimate birth weight 0 to 35 days after ultrasonographic examination. For each model, R^2 approached 1.0. The generated equations were tested on 167 nonmodel cases. Among the three best equations, 65% to 67% of estimates were within 100 mg/kg birth weight. The mean absolute error ranged from 86 to 91 gm/kg. With a mean lapse time of 16.8 ± 11 days, the accuracy of birth weight estimates equaled or exceeded that reported for existing static formulas. The accuracy of the estimates was maintained across the entire range of lapse times and birth weights observed. In intrapartum situations when ultrasonography is unavailable or technically difficult, birth weight can be estimated from remote ultrasound parameters. (AM J OBSTET GYNECOL 1989;161:742-7.)

Key words: Ultrasonography, estimated fetal weight

In a previous report[1] we described the development of an equation to predict birth weight from ultrasonographic examinations. By incorporating the interval from ultrasonographic examination to delivery (lapse time), the model predicted birth weight based on ultrasonographic measurements taken as early as 35 days before delivery. The rationale for the model was based on the hypothesis that ultrasonographic measurements of fetal dimensions at a point in gestation could be coupled with elapsed time to mathematically predict a birth weight based on observed growth in a population.

We extrapolated this concept to five existing formulas by including a lapse-time modifier in the structure of these existing equations. The lapse-time modifier for each equataion was determined individually from model building that analyzed the initial static estimate and the lapse time that occurred versus actual birth weight.

Material and methods

This study had two phases. In phase I, model building generated new equations based on five static equations. In Phase II, the new equations were tested on cases other than model cases.

Phase I—Model development. The records of all patients seen in the Perinatal Unit of the University of South Alabama Medical Center between October 1984 and September 1986 for obstetric ultrasonographic evaluation were reviewed. The patient population was a racially mixed (55% black), low-income clinic population. Patients were included in the study if they met the following criteria: (1) the pregnancy was a singleton gestation; (2) the biparietal diameter, occipitofrontal diameter, femur length, transverse and anteroposterior diameters of the fetal abdomen had been measured by ultrasonography; (3) data on the outcome of the delivery were available; (4) the interval (lapse time) from ultrasonographic examination to delivery was ≤35 days; and (5) birth weight was ≤5000 grams.

All ultrasonographic examinations were performed by one of three experienced ultrasonographers using a linear array real-time scanner (ADR Model 4000) with a 3.5 MHz transducer. As in our previous study,[1] standard imaging and measurement techniques were used.

Model generation and all statistical methods were performed with the Statistical Analysis System (SAS) and the IBM-4341-II mainframe computer of the University of South Alabama. Multiple linear regression using the least squares method was used to construct the models. Using the five formulas (Table I), the fetal weight estimates determined on the day of ultrasonographic examination (in logarithmic form) and the

lapse time observed were analyzed versus the logarithm of actual birth weight. For each equation the constructed model generated a lapse-time modifier.

After model development, the modified equations were tested with the model cases. The mean error (estimated − actual birth weight), mean absolute error (absolute value of estimated − actual birth weight), and the standardized absolute error (absolute error/kilogram birth weight) were determined for each modified equation. The equations were examined for accuracy across the range of birth weights and lapse times observed. To allow comparisons to previous reports, the observed error was converted to percentage error by the formula ([predicted weight − actual weight]/actual weight × 100) to generate a mean ± SD of percent error. The correlation coefficient (Pearson's *r*) of estimated versus actual birth weight was determined, and the percent of estimates within 50, 100, and 150 gm/kg of actual birth weight was calculated. One- and two-way analyses of variance were used to test for differences among means. Tukey's studentized range test was used to evaluate differences among group means. The significance level was set at alpha = 0.05.

Phase II—Model validation. The modified equations were validated by use of different cases from those used to develop the models. Patients seen in the Perinatal Unit for fetal ultrasonographic evaluation from October 1986 to August 1987 were reviewed for inclusion in the validation phase of the study. The inclusion criteria and ultrasonographic method were unchanged from phase I. Modified equations developed in phase I were used to generate birth weight estimates that were compared to actual birth weight. Accuracy of the estimates was determined as outlined in phase I.

Table II. Descriptive statistics of included cases for both phases of the study*

Variable	*Model development (N = 245)*	*Validation (N = 167)*

Birth weight in grams. *LT*, Lapse time in days.

Phase I—Model development. From 259 ultrasonographic examinations for which delivery outcome was known, 245 examinations and paired delivery outcomes fulfilled the study criteria. Table II presents the descriptive statistics of these cases.

A model to predict birth weight from remote ultrasonographic examination was generated for each of the five equations. For each model, R^2 approached 1.0. In each, the intercept did not differ significantly from zero and was deleted from the modified equation (Table III). The coefficients for each model's parameters are described in Table IV. Both lapse time and the logarithm of the initial fetal weight estimate contributed significantly to the birth weight predictions, $p \leq 0.0001$.

The modified equations were tested on the model cases. Modified equations 1, 2, and 3 performed quite similarly. Remarkably accurate birth weight estimates were noted. For each estimate, the mean error was very small and did not differ statistically from zero. The percent mean error was <1%. The mean absolute error per kilogram actual birth weight was less than 100 gm/kg. There was no significant difference in the ac-

curacy of estimates with increasing lapse time. In contrast, although the mean error for modified equations 4 and 5 did not differ statistically from zero, the percent mean error was between 1% and 2%, and the mean absolute error per kilogram actual birth weight exceeded 100 gm/kg for both. The accuracy of estimates was not stable over the range of lapse times for modified equation 4 nor over the range of birth weights for either modified equations 4 or 5.

Phase II—Model validation. One hundred sixty-seven cases fulfilled the study criteria for the validation phase. The descriptive statistics are presented in Table II.

Table V shows the overall accuracy of the modified equations. Modified equations 1, 2, and 3 again proved superior to 4 and 5. The accuracy of individual estimates, as best expressed by absolute error and standardized absolute error, was larger for the modified

equations 4 and 5 when compared with equations 1, 2, and 3.

The ability of the modified equations to maintain accuracy over the range of lapse times observed is presented in Table VI. For each modified equation, analysis of variance for differences among lapse time group segments failed to demonstrate differences for mean error, mean absolute error, or mean absolute error per kilogram birth weight ($p > 0.05$). In other words, increasing lapse time caused no deterioration in the accuracy of estimates.

Table VII shows the data on the accuracy of estimates across the range of birth weights encountered. Equations 1, 2, and 3 were consistently accurate across the range of birth weight groups, with no significant differences noted for mean absolute error or mean absolute error per kilogram birth weight (analysis of variance $p > 0.05$). A trend toward overestimating the weight of small infants as expressed by percent mean error was seen with equation 1 ($p = 0.09$) and equation 2 ($p = 0.07$) and was significant for equation 3 ($p = 0.02$). The estimates of equations 4 and 5 were not stable across weight groups for each measure of accuracy considered ($p < 0.005$).

In Table VIII, the estimates from the original static equations are compared with the estimates from the modified equations for patients delivering within 1 week of examination. The new equations, which adjusted for a mean lapse time of 3.1 ± 1.8 days, were associated with a notable reduction in mean error, percent mean error, mean absolute error, and maximum observed error. For each equation the modification less-

Table IX. Validation phase—Percent of birth weight estimates noted within 50, 100, and 150 gm per kilogram actual birth weight (n = 167)

Equation	Estimates (%) within		
	50 gm/kg	100 gm/kg	150 gm/kg
1	32.3	64.7	83.8
2	31.1	65.9	83.8
3	29.9	65.9	82.0
4	20.4	43.1	59.9
5	19.2	39.5	61.1

ened the overall tendency to underestimate birth weight.

The relative accuracy of each modified equation is shown in Table IX as the percent of each equation's estimates that fall within ranges of absolute error per kilogram birth weight. The performance of equations 1, 2, and 3 were virtually identical to each other; 65% to 67% of the estimates fell within 100 gm/kg actual birth weight. The estimates of equations 4 and 5 were considerably less accurate.

Comment

The remodeling of existing static equations to predict birth weight from remote ultrasonographic data was successfully accomplished. The accuracy of each equation's conversion was directly related to the accuracy of its original static estimate. The relative inaccuracy of the modified equations 4 and 5 is heralded by the less accurate predictions made by the parent static formulas (Table VIII).

The accuracy of birth weight predictions of the modified equations 1, 2, and 3 is remarkable and compares favorably to other studies of static formulas. Shepard, et al.[2] reported that 54.8% and 50.7% of the estimates from equations 1 and 2, respectively, were within 100 gm/kg birth weight. Warsof et al.[3] reported four equations with percent of estimates within 100 gm/kg that ranged from 52% to 57%. Weiner et al.[4] evaluated the use of eight formulas with preterm infants; the percent of estimates within 100 gm/kg ranged from 19% to 63%. In each of these studies the estimates were made within 48 to 72 hours of delivery. In this study 65% to 67% of the estimates were within 100 mg/kg birth weight. Warsof et al.[3] reported the mean absolute error per kilogram birth weight to range from 104 to 125 gm/kg among four equations tested. The modified equations 1, 2, and 3 had mean absolute errors that ranged from 86 to 91 gm/kg. Equations 1 and 2 (from Hadlock et al.[5]) may offer advantages over our previously reported equation[1] as a result of improved accuracy across birth weight ranges.

Hadlock et al.[5,6] reported 19 static formulas in which the standard deviation of percent mean error ranged from ±7.3% to 12.9%. Ott et al.[7] observed a range from 13% to 18% for the same statistic among eight formulas. The same authors noted a range from ±8.7% to 11.1% among six other formulas.[8] In this study, the standard deviation of percent error ranged from ±10.1% to 10.8% for the three modified formulas derived from Hadlock et al. Shephard et al.[2] reported the mean absolute error to be ±343.4 and ±349 gm for their equations 1 and 2 for all estimates, and a maximum absolute error observed of 1266 and 1099 gm, respectively, for each equation. The mean absolute error for the modified formulas 1 through 3 was <280 gm, and the maximum absolute error ranged from 962 to 1288 gm (Table V).

The results of this study validate the concept of incorporating a lapse-time factor in equations to predict birth weight from remote ultrasonographic data. Weight estimates were improved even when birth occurred within 1 week of ultrasonographic examination. The accuracy of the estimates was maintained across the full range of lapse times observed. When lapse time exceeded 35 days, unacceptable deterioration of accuracy is noted (our unpublished observations). The use of these equations when lapse time exceeds 35 days is discouraged. Although the number of modified equations is limited, this concept probably could be used to remodel virtually any static formula.

These modified equations predict growth subsequent to ultrasonographic examination on the basis of the mean growth observed in our population. Although no attempt was made to exclude growth-retarded or macrosomic infants during model development, the use of the modified equations for pregnancies at risk for excess or subnormal fetal growth may result in significant overestimation or underestimation. Furthermore, these equations have been tested only as birth weight predictors, and their accuracy remote from delivery for interval weight estimations is not suggested, implied, or tested. Rates of fetal growth remote from delivery may differ from that in the 35 days before delivery.

The clinical use of the modified equations is straightforward. The weight estimate determined by the static parent formula is coupled with the lapse time that has occurred, and a birth weight estimate is determined by the modified form of that equation.

The results achieved in this study and the parameter coefficients determined may be specific to our population. Full validation of the modified equations requires testing outside our population. Although the concept of lapse-time factoring may be confirmed by others, the coefficients for the equations' parameters may differ in other populations.

Dating the early pregnancy by sequential appearance of embryonic structures

Wendy B. Warren, MD, Ilan Timor-Tritsch, MD, David B. Peisner, MD, Sashi Raju, and Mortimer G. Rosen, MD

New York, New York

A total of 97 transvaginal scans were performed from 4 to 12 weeks' gestation in normal and accurately dated gestations. The sequential appearance of six structures were examined: (1) the gestational sac only was present during week 4; (2) the yolk sac appeared in week 5; (3) the fetal pole with detectable heart motion was first seen in week 6; (4) the single unpartitioned ventricle in the brain marked week 7; (5) the falx cerebri appeared during week 9; and (6) the appearance and the disappearance of the physiologic midgut herniation were seen in week 8 and week 11, respectively. Inasmuch as the time in gestation at which these structures appear characterizes the gestational age more than any measurement at this age, we propose a practical method to determine the correct gestational age in early first-trimester pregnancy. (AM J OBSTET GYNECOL 1989;161:747-53.)

Key words: Transvaginal ultrasonography, embryologic development, pregnancy, first trimester

Pregnancy dating is an important consideration in several diagnostic and therapeutic processes in perinataology. The later in pregnancy the "dating" process is performed, the larger the confidence limits become.[1] Measurement of the crown-rump length by ultrasonography is considered to be the most accurate method to establish gestational age in the first trimester. However, crown-rump length is measurable by abdominal ultrasonography only after 6½ weeks' gestation.[2-5] The accuracy of early first-trimester crown-rump length measurements by abdominal ultrasonography has been estimated to be ±5 days at best.[6] Attempts have been made to date the very early gestation by measuring the size of the gestational sac.[1, 7] However this was not widely accepted as a useful clinical tool because the confidence limits of these measurements are ±12 days and the size of the sac varies because of variable influences of the bladder and scanning plane.[1]

In earlier publications we described the ability of a 6.5 MHz transvaginal transducer probe to image embryonic and extraembryonic structures in the first trimester.[8] In early anatomic studies of human embryos, the structures of developing embryos have been used as a method to determine their postconceptional age.[9, 10] We hypothesize that the sequential appearance

of embryonic structures by transvaginal ultrasonography can be used in the dating process of first-trimester pregnancies. The purpose of this study is to develop an ultrasonographic method of dating for practical clinic application in the first trimester.

Material and methods

We performed 104 first trimester transvaginal ultrasonography examinations. For purposes of cross-sectional analysis in this study, only one examination for each embryo-fetus was used. To ensure the enrollment of patients with most accurate dating, we included only patients who had artificial insemination, participated in our in vitro fertilization program, or had regular menstrual periods with certain dates of their last menstrual period (LMP) or conception.

Gestational ages in this study are given in weeks and days from the LMP or from the day of conception to which 14 days were added. For the purpose of analysis and potential clinical application, the studies were grouped by weeks of gestational age (e.g., 4 weeks = 4 weeks and 0 days to 4 weeks and 6 days).

The ESI-1000 scanner (Elscint, Haifa, Israel) equipped with the ED65 transvaginal probe with a 10 mm diameter crystal that has a frequency of 6.5 MHz was used for all studies. To shorten examination time,

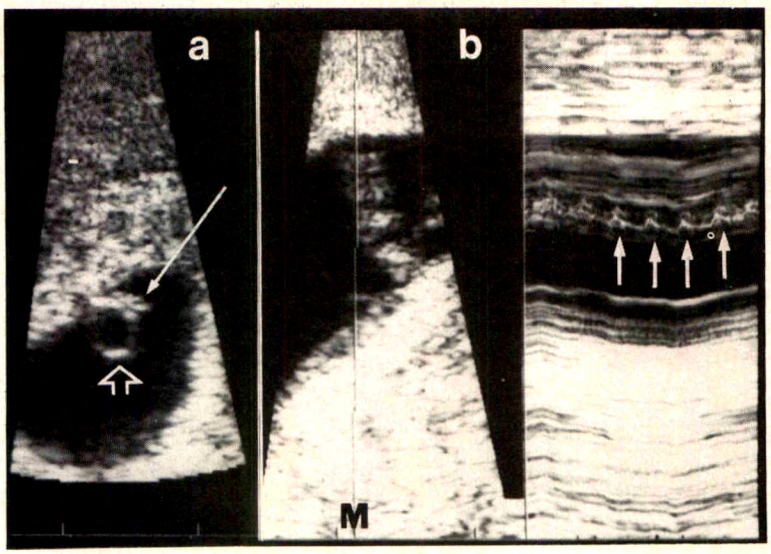

Fig. 3. Week 6. **a,** 4 mm Embryonic pole *(long arrow)* is imaged tangentially to yolk sac *(open arrow)*. **b,** M-mode cursor *(M)* clearly shows heart motion *(small arrow)*.

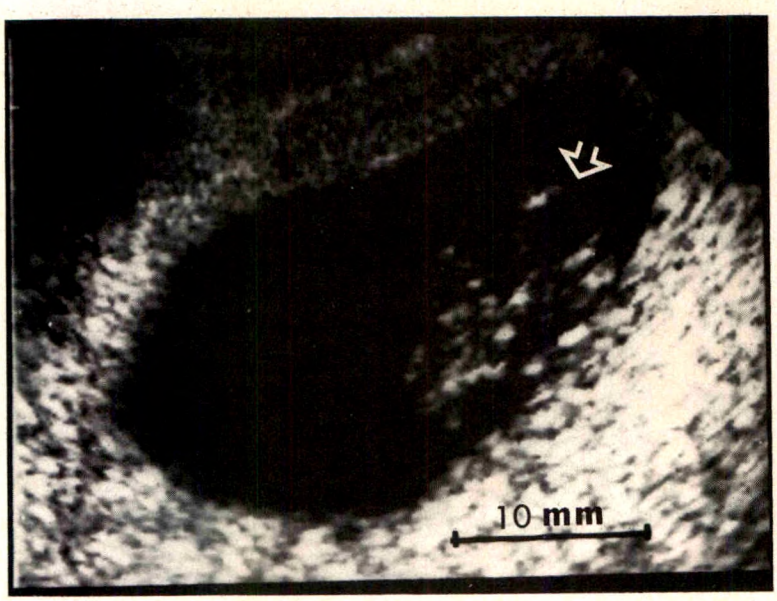

Fig. 4. Week 7. Unpartitioned ventricle in head *(open arrow)*.

video recording of the scanning session was used in gestations >9 weeks. The reason for this was that fetal movement starts to be significant at this time, interfering with a detailed, effective, and short examination.

The hard copies and the video tape recordings of each gestation were evaluated for the presence and the absence of six embryonic-anatomic structures known to occur at certain gestational ages: (1) the gestational sac (Fig. 1); (2) the yolk sac (Fig. 2); (3) fetal pole with detectable heart motion (Fig. 3); (4) the single unpartitioned ventricle in the developing brain (Fig. 4); (5) the falx that divides the ventricle (Fig. 5); and (6) the physiologic midgut herniation (Fig. 6).

Results

Table I contains the distribution of the scanned pregnancies throughout gestation.

For each gestational week the mean gestational age by crown-rump length was compared to the mean gestational age as determined clinically by date of conception. Table I shows that the clinical dating for each week >6 weeks' gestation is within 1 day of the gestational

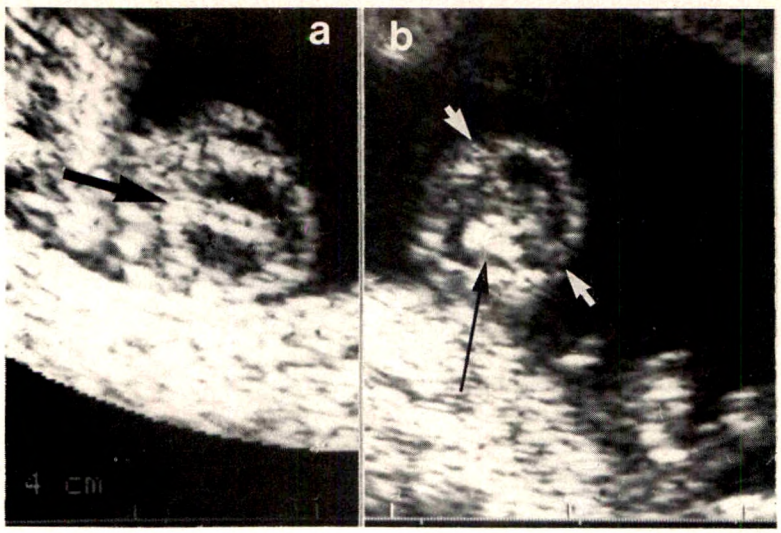

Fig. 5. Week 9. **a,** Falx *(black arrow)* divides ventricle. **b,** In addition to falx *(white arrows)*, hyperechogenic choroid plexus is visualized *(black arrow)*.

age derived from the measured mean crown-rump length.[2] At 11 weeks' gestation, however, gestational age by LMP was within 2 to 3 days of the gestational age by crown-rump length.

As to the presence or the absence of embryonic and extraembryonic structures, the following observations were made.

Week 4, n = 6. The sonolucent intrauterine gestational sac without a yolk sac was seen throughout week 4. The earliest observation was in three patients at 4 weeks and 3 days. The latest this observation was made was at 5 weeks and 1 day (one patient).

Week 5, n = 11. The yolk sac is the dominant structure of week 5. It was observed as early as 5 weeks and 0 days in three patients. The latest a yolk sac was seen with no heart motion in a fetal pole was at 6 weeks and 1 day.

Week 6, n = 15. The fetal pole with fetal heart motion was first seen in week 6. In two embryos the fetal heart was seen as early as 6 weeks and 0 days.

Week 7, n = 17. The appearance of the undivided ventricle in the forebrain marks 7 weeks' gestation. Some variation was observed; in two instances the single ventricle appeared as early as 6 weeks and 6 days. In one embryo this structure with no falx was seen as late as 9 weeks and 2 days.

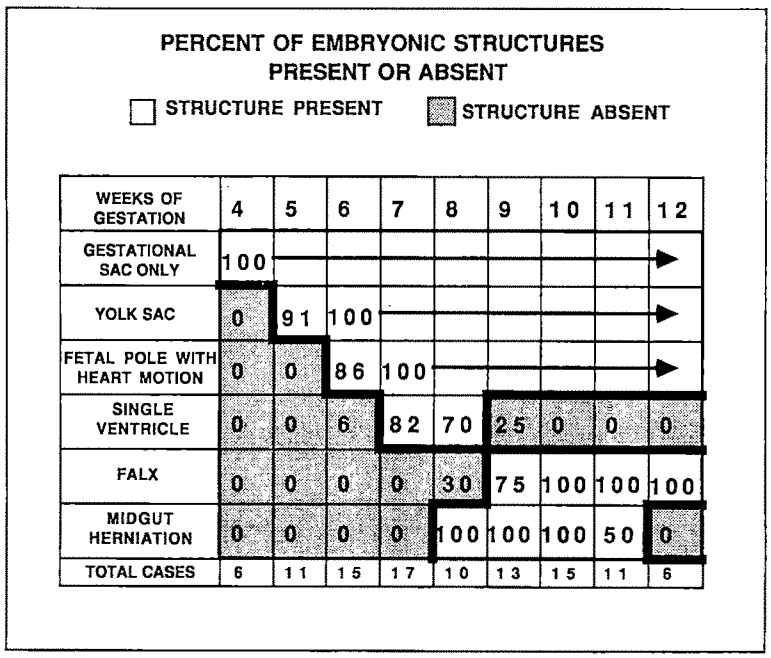

Fig. 7. Summary of detection of six embryonic structures in first trimester of pregnancy. *Solid line* differentiates weeks of gestation in which majority of embryos-fetuses displayed change in ultrasonographic appearance.

Table I. Distribution of the patient population according to weeks' gestation by clinical dating and by mean crown-rump length

Week	*No.**	*Mean gestational age by clinical dating*	*Mean crown-rump length† (mm)*	*Gestational age by mean crown-rump length† (weeks + days)*
4	6	4 + 4	—	—
5	11	5 + 2	2.0‡	—
6	15	6 + 2	6.4	6 + 3
7	17	7 + 3	11.8	7 + 4
8	10	8 + 3	17.4	8 + 3
9	13	9 + 2	26.1	9 + 3
10	15	10 + 2	34.5	10 + 2
11	11	11 + 2	48.0	11 + 5
12	6	12 + 3	53.0	12 + 3

*Total = 104.
†Crown-rump length by Robinson and Fleming.[2]
‡$n = 2$.

Week 8, n = 10. The falx appeared and divided the two lateral ventricles scanned in week 8 in three of 10 embryos. The earliest the falx was seen was at 8 weeks and 1 day. The physiologic ventral herniation of the midgut was observed in all four embryos in which the abdominal wall was imaged.

Week 9, n = 13. During week 9, 10 of 13 fetuses showed the presence of the falx partitioning the ventricle. In all 13 fetuses the physiologic midgut herniaton was present.

Week 10, n = 15. In week 10 all the fetuses showed the falx in the forebrain. The area of the cord insertion could be evaluated in 11 of 15 fetuses and the midgut herniation was seen in all 11 fetuses.

Week 11, n = 11. In week 11, the midgut herniation was present in four of eight fetuses in which the umbilical cord insertion was imaged.

Week 12, n = 6. No fetus showed a midgut herniation after 12 completed weeks' gestation.

Comment

In a study of human embryo specimens accumulated at the Carnegie Institution of Washington, Johns Hopkins University, Streeter[10] used the number of somites

present in the embryos to classify their stage of development into groups. For each group, he carefully described the development of organ systems in an attempt to determine the age. He used this structural method to determine age because, "It is in embryos of the first seven weeks that the external form and structural organization are more informative as to age than is size alone." Beyond 8 weeks from conception, according to Streeter, "the weekly increment in growth and weight is large enough to provide an adequate index of relative development."

Obstetric transvaginal ultrasonography allows the use of the high-frequency, 6.5 MHz probe with a lateral resolution of about 0.6 mm and axial resolution of 0.3 mm.[11] This type of high resolution enables the accurate measurement of extremely small structures such as 2 mm yolk sac and the early embryonic pole, and the detection of even thinner structures at fluid interfaces, such as the falx, as we have described in previous studies.[8] We used six embryonic structures detected by transvaginal ultrasonography for purposes of dating the early pregnancy with consideration to the hypothesis of Streeter that this could be a useful method to date the gestation.

After testing the accuracy of the gestational ages of our study groups by crown-rump length, we were confident to expand the evaluation to the six embryonic structures imaged throughout the group.

Despite our efforts to accurately date every pregnancy included in the study, there were several embryos that were slightly different from the overwhelming majority of the embryos of the same gestational age. The following is a list of examples:

1. In one embryo at 6 weeks and 1 day, only a yolk sac was seen. This was commonly observed during week 5.
2. In two embryos the single ventricle, usually seen during week 7, was seen at 6 weeks and 6 days.
3. In one embryo an unpartitioned ventricle with no falx was seen as late as 9 weeks and 2 days.
4. In one case the falx, which marks the week 9, was seen as early as 8 weeks and 1 day.

These slight variations seen in a small percentage of the studied embryos may be a result of unforeseen variations in the actual gestational ages despite our best effort to control this variable. Theoretically, they may also represent some minor differences in timing of the actual structural development as Streeter suspected.[10]

We therefore suggest a practical way to date the early first-trimester pregnancy, summarized in Fig. 7. For each of the six anatomic structures analyzed, we placed a dividing mark between the gestational weeks during which the anatomic structure was seen in the majority of cases and the weeks during which it was mostly absent. From these lines we have derived a steplike map for easy dating purposes.

When a gestational sac is visualized without a yolk sac, the gestation is in week 4 from the LMP. If a yolk sac is detected in the gestational sac, but no fetal heart can be discerned, the gestation is in week 5. If there is fetal heart motion, but a cerebral ventricle cannot be visualized, then the gestation is in week 6. If there is a single ventricle but no falx and no physiologic midgut herniation, then it is 7 weeks' gestation. If either a falx or the midgut herniation can be seen, it is >8 weeks' gestation. If there definitely is no midgut herniation, the normal fetus is >12 weeks' gestation (Fig. 7). The converse is also true—if a ventral hernia is imaged in a well-dated fetus >12 weeks' gestation, this should be considered abnormal or, at the least, highly suspicious.

These normative data may also be used to follow-up expected development and detect as early as possibly any deviation from the normal. In studies done in basic embryology it has been suggested that structure definition within any given embryo-fetus is at least as reliable, and probably is more reliable, than the currently employed length measurements to determine gestational age in the early pregnancy. More work is needed to prove this assumption as it applies to ultrasonographic techniques to date the early pregnancy.

In conclusion:

1. The high-frequency high-resolution vaginal ultrasound probe detects certain embryonic structures at consistent gestational ages.
2. Accurate dating of early pregnancies by this technique is feasible based on the chronologic and sequential appearance of these structures.
3. We propose a simple chart as a practical dating guide for clinical use in the first-trimester pregnancy with uncertain dates or to monitor the structural development of an embryo-fetus with known and accurate dating. A line was drawn to mark the gestational weeks during which a majority of the embryos-fetuses displayed a change in the ultrasonographic appearance. (Fig. 7)

Macrosomia in the postdate pregnancy: Is routine ultrasonographic screening indicated?

Judith L. Chervenak, MD, Michael Y. Divon, MD, Jordan Hirsch, MD, Barbara A. Girz, DO, and Oded Langer, MD

Bronx, New York, and Newark, New Jersey

Macrosomia is a potential but often overlooked consequence of the postdate pregnancy. A total of 317 consecutive patients with well-dated pregnancies who were seen because of fetal surveillance at >41 weeks' gestation had an estimation of the fetal weight based on femur length and abdominal circumference at the initial visit. The incidence of macrosomia at 41 weeks' gestation was 25.5%. There was a higher incidence of cesarean section because of arrest and protraction disorders in the postdate pregnancies in which the infant was macrosomic (22%) versus those in which the infant was not macrosomic (10%, $p < 0.01$). In a control group of 100 consecutive women delivered between 38 and 40 weeks' gestation, the incidence of macrosomia was 4%, significantly lower than the rate in the postdate patients ($p < 0.01$). Incidence of cesarean section because of arrest and protraction disorders was significantly lower in this group (6%, $p < 0.05$). The sensitivity and specificity of an estimated fetal weight >4000 gm to predict a birth weight >4000 gm were 60.5% and 90.7%, respectively, with a positive predictive value of 70% and a negative predictive value of 87%. We conclude that routine ultrasonographic screening for macrosomia may be a valuable adjunct to current fetal surveillance protocols used in the postdate pregnancy. (AM J OBSTET GYNECOL 1989;161:753-6.)

Key words: Fetal weight, macrosomia, postdates, ultrasonography

Approximately 18.5% of all pregnancies continue beyond 41 weeks' gestation and 3.9% to 10% continue beyond 42 weeks' gestation.[1] These pregnancies have an increased risk of perinatal morbidity and mortality that can be reduced with appropriate antepartum fetal surveillance.[2]

There is no consensus with regard to the optimal form of fetal surveillance to use in the postdate pregnancy. Current protocols suggest the use of the biophysical profile, nonstress test, contraction stress test, amniotic fluid index, umbilical artery Doppler systolic/diastolic ratio, or some combination of the above.[3-5] These tests are primarily designed to detect fetal hypoxia or acidosis as a result of uteroplacental insufficiency.

Another recognized but often overlooked consequence of the prolonged pregnancy is fetal macrosomia. The postdate fetus should continue to grow, although at a reduced rate, in the absence of uteroplacental insufficiency.[6] Thus an otherwise healthy fetus may become macrosomic with continuation of the pregnancy. Macrosomia, although rarely screened for unless clinically suspected, is by itself associated with an increased risk of maternal and perinatal morbidity and mortality. The purpose of this study was to determine (1) the incidence of macrosomia in pregnancies ≥41 weeks' gestation, (2) the incidence of cesarean section because of arrest and protraction disorders in this sub-

set of patients, and (3) the predictive value of a single ultrasonographically determined estimated fetal weight as a routine screening tool for macrosomia in the postdate pregnancy.

Material and methods

The study group consisted of all patients seen for fetal surveillance at >41 weeks' gestation from January 1987 through June 1988 at a hospital that serves a private middle-class population. Only patients with singleton uncomplicated pregnancies with intact membranes were included in the study. Gestational age was confirmed by early first examination and ultrasonogram at <20 weeks' gestation in patients with certain last menstrual periods. All patients had negative glucose screen results at 26 to 28 weeks' gestation.

After the initial visit, these patients were routinely seen twice weekly to undergo nonstress tests and ultrasonographic determination of amniotic fluid volume.

Morphometric measurements were made with the use of real-time scanning equipment (either an ATL-Ultramark IV, ATL, Bothell, Wash., or an Aloka 633, Cozometrics, Wallingford, Conn.). At that time, measurements of biparietal diameter (BPD), femur length, and abdominal circumference were made with standard techniques. Estimated fetal weights were determined with the standard equation of Hadlock, which is based on measurements of the abdominal circumference and femur length. Estimated fetal weights were not used as part of a management protocol. Actual birth weight, route of delivery, and indications for cesarean section were determined. Percentage differences between estimated and actual birth weights were determined for each patient. The sensitivity, specificity, and positive and negative predictive values of an estimated fetal weight >4000 gm to predict a birth weight >4000 gm were determined.

The postdate patients were compared with a control group of 100 consecutive patients between 38 and 40 weeks' gestation who had no antepartum complications. These patients were drawn from the same patient population. The incidence of macrosomia, which was defined as a birth weight >4000 gm, was determined for both groups. The incidence of cesarean section because of protraction and arrest disorders was determined for the study group with birth weights above and below 4000 gm, as well as for the control group.

A protracted active phase was defined as cervical dilatation of <1.2 cm/hr in nulliparous patients and <1.5 cm/hr in multiparous patients. A prolonged deceleration phase was defined as >1 hour for multiparous women and >3 hours for nulliparous women. A protracted descent was defined as <1.0 cm/hr and <2.0 cm/hr in nulliparous and multiparous patients, respectively. Arrest of dilatation was defined as no progress in dilation for >2 hours during the active phase of labor. Arrest of descent was defined as no progress in descent >1 hour for nulliparous women and >0.5 hour for multiparous women.[7]

Results

A total of 472 patients were seen for fetal surveillance of their pregnancies at >41 weeks' gestation between January 1987 and June 1988. Of these, 317 patients met criteria for the study. The mean gestational age was 42 ± 0.6 weeks' gestation and the mean birth weight was 3710 ± 452 gm. There were 236 patients (74.4%) who were delivered of infants who weighed <4000 gm. A total of 81 patients (25.5%) were delivered of infants who weighed >4000 gm; 12 of these 81 patients were delivered of infants who weighed >4500 gm and 3 were delivered of infants who weighed >5000 gm.

There were 172 patients (54.2%) who had completed 41 weeks' gestation. A total of 145 (45.7%) patients had completed 42 weeks' gestation, 19 of whom had completed 43 weeks' gestation. The mean birth weight of the infants born at 41 completed weeks' gestation was 3710 ± 452 gm and the mean birth weight of infants at 42 weeks' gestation was 3705 ± 454 gm. Of the 172 neonates (25.5%) born at 41 weeks' gestation, 44 were macrosomic; 37 of the 145 neonates (25.5%) born at >42 weeks' gestation were macrosomic. There was no perinatal mortality.

The control group had a mean gestational age of 39.8 ± 0.5 weeks and a mean birth weight of 3339 ± 360 gm. The incidence of macrosomia was 6%, significantly less than in the study population ($p < 0.05$).

Of the 317 patients in the study group, 76 were delivered by cesarean section, of which 72 were primary and 4 were repeat. The incidence of primary cesarean section was 22.7%. In those with birth weights >4000 gm, 18 of 81 (22%) had cesarean sections because of arrest or protraction disorders. In those with birth weights <4000 gm the incidence of cesarean section for the same indications was 24 of 235 (10%), which was significantly lower ($p < 0.01$). Eight patients (2.5%) had outlet forceps deliveries, of which five were performed on infants <4000 gm and three involved infants >4000 gm. This was not significantly different. There were no midforceps deliveries. The incidence of cesarean section because of arrest or protraction disorders in the control group was 4%, which again was significantly lower when compared with the incidence for the postdate group in general ($p < 0.05$).

There were 66 patients (20.8%) in whom the BPD was not obtainable because of the position of the fetal head. Abdominal circumference and femur length were obtained in all patients. There were 276 patients

(87%) who had an estimated fetal weight based on the abdominal circumference and femur length that was within 15% of the actual birth weight. Of these, 216 (68%) had estimated weights within 10% of the actual birth weight. Of the 251 patients in whom an estimation of fetal weight based on BPD and abdominal circumference could be obtained, 221 (88%) had an estimate within 15% of the actual birth weight and 176 (70%) had an estimate within 10% of the actual birth weight. Table I presents the sensitivity, specificity, and positive and negative predictive values of an estimated fetal weight >4000 gm to predict a birth weight >4000 gm. The mean interval from scan to delivery was 5.4 ± 4.4 days and the mean percentage error of an estimated fetal weight was 7.5% ± 6.4%.

Table I. Predictive value of estimated fetal weight

	Birth weight	
Estimated fetal weight	*>4000 gm*	*<4000 gm*
>4000 gm	49	22
<4000 gm	32	214

Sensitivity = 61%; specificity = 91%; positive predictive value = 70%; negative predictive value = 87%.

Comment

Results of this study indicate the incidence of macrosomia at ≥41 weeks' gestation is considerable. The incidence of birth weights >4000 gm was 25.5% (44:172) at 41 weeks' gestation and 25.5% (37:145) at 42 weeks' gestation. This was significantly increased when compared with the 6% of macrosomic infants in the control group of patients delivered between 38 and 40 weeks' gestation ($p < 0.05$). Similar results were reported by Arias[8] who also found a 23.8% incidence of macrosomia in fetuses of >41 weeks' gestation. In a review of 9394 pregnancies, Boyd et al.[9] found a 16% incidence of macrosomic infants at 41 weeks' gestation and a 21% incidence at 42 weeks' gestation, both of which were significantly increased when compared with the 8.2% incidence he reported at <41 weeks' gestation. This study concluded that infants delivered at 42 weeks' gestation were almost three times as likely to weigh >4000 gm than those delivered at <41 weeks' gestation.
